CHAPTER 110

COMPLICATIONS AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION

Navneet S. Majhail and Daniel J. Weisdorf

The high-dose therapy used in hematopoietic cell transplantation (HCT) results in toxicities induced directly by the treatment and secondarily by the prolonged immunodeficiency and extended recovery process. Identification of risk factors for particular complications allows the design of risk-specific supportive care regimens that may reduce the rates of morbidity and mortality accompanying transplantation. HCT-related complications can be broadly classified into infections, early noninfectious complications (within 3 months of HCT), late noninfectious complications (after 3 months of HCT), and graft-versus-host disease (GVHD) (Table 110-1).

INFECTIONS

Infections are among the foremost causes of nonrelapse mortality in HCT recipients and can cause significant morbidity, both in the early and late transplant period (Table 110-2). Immune defects occurring in the posttransplant period can be divided into predictable phases based on time from engraftment (sustained absolute neutrophil count >500/μL), with characteristic infections in each phase (Fig. 110-1). Antimicrobial prophylaxis regimens tailored to address the risk for specific infections during these time periods are effective in decreasing the incidence of posttransplant opportunistic infections (Table 110-3). Evidence-based guidelines for preventing infectious complications among HCT recipients have been published and can be used as a reference for determining infection risk and assigning antimicrobial prophylaxis for an individual patient.[1]

Engraftment generally occurs within 7 to 14 days in autologous and 14 to 28 days in allogeneic HCT recipients. Recipients of grafts from unrelated donors (URDs) or umbilical cord blood (UCB) tend to engraft later compared to sibling donors; more importantly 5% to 10% of unrelated-donor and 5% to 20% of UCB grafts may fail to engraft, leading to prolonged neutropenia and extended transfusion dependence. The main risk factors for infection during this preengraftment phase are disruption of mucocutaneous barriers and indwelling venous catheters. Bacterial infections can occur in up to 30% of transplant recipients during this initial period and usually arise from normal flora of the skin (coagulase-negative *Staphylococcus*), oropharynx, and gastrointestinal tract (viridans streptococci, *Enterococcus* spp., and enteric gram-negative bacilli).[2] Colonizing yeasts or molds also invade because of neutropenia and disruption of normal host flora and can lead to systemic mycotic infections (most often *Candida* spp. or *Aspergillus* spp.) in 10% to 15% of patients.[3] Reactivation of herpesviruses can occur in the absence of prophylaxis.

The predominant defects seen in the early to late postengraftment period are impairments of cellular and humoral immune systems.[4] This state of underlying severe immune dysfunction is enhanced and prolonged by acute and chronic GVHD and by corticosteroids and by the immunosuppressive agents used for GVHD prevention and treatment.[5,6] The incidence of late opportunistic infections is much lower in autologous HCT recipients because of quicker immune reconstitution and the lack of immunosuppressive drugs. Immune reconstitution can take up to 2 years to fully recover in allogeneic HCT recipients. Patients with chronic GVHD can be functionally asplenic and be at risk for infections by encapsulated bacteria. In addition, chronic GVHD patients on long-term immunosuppression are susceptible to fungi (*Aspergillus* spp., *Candida* spp., and *Pneumocystis jiroveci*) and viruses (cytomegalovirus [CMV] and varicella-zoster virus [VZV]).[7] Additional factors that can delay immune reconstitution include donor-recipient human leukocyte antigen (HLA) disparity, graft manipulation with depletion of T cells in vitro or using antithymocyte globulin (ATG) or alemtuzumab in vivo, and use of URDs and possibly UCB as a graft source.[5,8,9] Antimicrobial prophylaxis should continue beyond the initial posttransplant period, typically for at least 3 to 6 months after cessation of all immunosuppression, especially in patients being treated for chronic GVHD. Some centers use total T-cell ($CD3^+$) and particularly $CD4^+$ cell levels as surrogate markers of T-cell immunity and to guide decisions regarding antimicrobial prophylaxis. Supplemental intravenous immunoglobulin (Ig) has been considered for patients with persistent hypogammaglobulinemia (IgG levels <400 mg/dL), but its prophylactic use is costly, does not prolong survival or prevent late infections, and may impair humoral immune reconstitution.[10,11] Patients with GVHD and those with indwelling venous access who undergo dental procedures should receive antibiotics similar to use for endocarditis prophylaxis.[12] Published guidelines are available for immunization of HCT survivors (Table 110-4).[1]

Based on the type and dose of conditioning chemotherapy and radiation, recipients of nonmyeloablative or reduced-intensity conditioning (NMA/RIC) regimens can exhibit varying degrees of myelosuppression.[13] The incidence of bacterial infections is lower in NMA/RIC recipients due to the shorter duration of posttransplant neutropenia.[14] However, the degree of lymphodepletion tends to be comparable to that seen with myeloablative regimens, and the risks of invasive aspergillosis and CMV reactivation remain unchanged.[15-18]

Among UCB HCT recipients, neutrophil engraftment and immune reconstitution can be delayed and a higher incidence of bacterial and viral infections in the early, but not later, posttransplant period has been reported.[19] The incidence of CMV reactivation ranges from 20% to 50%, but organ involvement by CMV is infrequent.[20,21] Recipient CMV serostatus is the most important predictor of CMV disease in this setting. UCB transplantation is associated with lower risks of chronic GHVD. Although detailed studies are lacking, the incidence of late infections using UCB grafts may be lower than what is seen after URD HCT. Overall, the risk for serious infections among children receiving UCB grafts is comparable to that of URD marrow and is lower than that of a T cell–depleted graft source.[22] Among adult UCB HCT recipients, the incidence of infections is higher in the early posttransplant period; however, infections do not clearly compromise the risks for overall and nonrelapse mortality compared to URD HCT.[22]

The approach to managing posttransplant infections is generally similar to that for infections in patients with cancer, especially leukemia (see Chapter 88). However, certain infections, particularly those due to viruses and fungi, are unique to the HCT population and are discussed in further detail here.

Febrile Neutropenia

A large proportion of patients develop fever in the early posttransplantation period, though an infectious pathogen is identified in only

Table 110-1 Major Complications of Hematopoietic Cell Transplantation

	Complication	Incidence
Infections	Bacterial infections	
	Gram-positive bacteremia	20%-30%
	Gram-negative bacteremia	5%-10%
	Viral infections	
	Cytomegalovirus	5%-40% in high-risk patients*
	Herpes simplex virus	5%-10% in seropositive patients
	Varicella-zoster virus	10%-50% in seropositive patients
	Respiratory viruses	10%-20%
	Fungal infections	
	Candida	5%-10%
	Aspergillus and other molds	5%-15%
	Pneumocystis jiroveci	<1%
	Other infections	
	Toxoplasma gondii	2%-7% in seropositive patients
Early noninfectious complications (0-3 mo)	Regimen-related toxicity	
	Mucositis	60%-75%
	Hemorrhagic cystitis	5%-10%
	Venoocclusive disease	5%-40%
	Pneumonitis	10%-20%
	Alveolar hemorrhage	5%-10%
	Graft failure	2%-10%
	Adverse drug reactions	Common
Late noninfectious complications (>3 mo)	Organ-specific late effects	
	Cataracts	25%-40%
	Hypothyroidism	30%-50%
	Sterility/hypogonadism	50%-90%
	Growth disturbances	30%-50% in prepubertal children
	Osteoporosis/avascular necrosis	5%-20%
	Malignant relapse	Variable
	Second cancers	2%-12%
Graft-versus-host disease	Acute	20%-50% with related donors, 40%-90% with unrelated donors, 20%-50% with UCB
	Chronic	20%-40% with related donors, 40%-70% with unrelated donors, 20%-40% with UCB

50% of patients. Fever may also be due to tissue inflammation (oropharyngeal or enteric mucositis), transfusions, amphotericin (though now used less frequently), or other drug fever. Bacterial infections due to aerobic bacteria such as viridans streptococci and enteric gram-negative bacilli are the primary concern during this neutropenic phase, although there is also an ongoing risk for infections with yeasts. Prophylactic strategies can include suppressive antimicrobials, against both bacteria and fungi.

Empiric therapy with broad-spectrum antibiotics is usually started at fever onset along with appropriate clinical and microbiologic evaluation. Choice of antibiotics depends on prior and current antibiotic usage modified by local resistance patterns and can be based on recommendations available for the treatment of febrile neutropenia in general cancer patients.[23] Among patients with persistent febrile neutropenia, that is, fever without an identified focus that continues despite 3 to 5 days of appropriate broad-spectrum antibiotics, invasive fungal infections should be considered.[24] Initiating empiric antifungal therapy with mold-active agents such as voriconazole, caspofungin, or amphotericin is generally recommended at this stage.[25] The choice of agent is dependent on prior exposure to antimold agents for prophylaxis where resistant species (e.g., *Zygomycetes*) may emerge. Empiric mold-specific therapy can be started earlier in patients who have experienced prolonged periods of neutropenia before HCT (e.g., patients with myelodysplastic syndromes). Repeated vigorous investigation to identify sources of infection (e.g., with computed tomographic [CT] scan of the chest and sinuses), even for fever recurring after initial defervescence, is essential. Although administration of myeloid growth factors (granulocyte colony-stimulating factor [G-CSF] or granulocyte-macrophage colony-stimulating factor [GM-CSF]) reduces the duration of neutropenia and accelerates engraftment, it has not been demonstrated to reduce mortality from early posttransplant infections.[26]

Cytomegalovirus Infection

Epidemiology and Risk Factors

Despite the introduction of effective antiviral therapies, CMV infection continues to be a major cause of infection-related morbidity and mortality in HCT recipients.[27] The risk for CMV reactivation spans both the early and late transplant period, especially in patients with GVHD on prolonged immunosuppression. Although the incidence of early CMV disease with organ involvement has declined to 3% to 6% with the use of empiric antiviral drug therapy directed by routine surveillance with CMV deoxyribonucleic acid (DNA) polymerase chain reaction (PCR) or antigenemia testing, late-onset CMV infection is still seen in up to 20% to 40% of patients.[28-30]

Seropositivity of the recipient is the most important risk factor for CMV infection in HCT recipients, and reactivation of latent virus is

Table 110-2 Common Infections in Hematopoietic Cell Transplant Recipients

Pathogen	Risk Period After HCT (wk)	Risk Factors	Common Clinical Syndromes	Treatment
Gram-positive cocci	1-4	Neutropenia Mucositis Central venous catheters Skin breakdown	Bacteremia	Antibiotics based on susceptibility testing
Enterobacteriaceae spp.	1-4	Neutropenia Skin breakdown GI mucosal breakdown	Bacteremia	Antibiotics based on susceptibility testing
Clostridium difficile	1-8	Antibiotics	Colitis	Metronidazole Oral vancomycin
Encapsulated bacteria*	>12	Chronic GVHD Chronic immunosuppression	Sinusitis Pneumonia	Antibiotics based on susceptibility testing

Table 110-4 Recommended Vaccinations for Hematopoietic Cell Transplantation Recipients

Vaccine*	Time After HCT to Initiate Vaccine	No. of Doses†
Pneumococcal conjugate	3-6 mo	2-3‡
DTaP§	6-12 mo	3
Haemophilus influenzae type b conjugate	6-12 mo	3
Inactivated poliovirus	6-12 mo	3
Recombinant hepatitis B	6-12 mo	3
Inactivated influenza	4-6 mo	1-2 yearly‖
Measles, mumps, and rubella virus (live)	24 mo	1-2¶
Varicella-zoster	24 mo	1¶

DTaP, Diphtheria and tetanus toxoids and acellular pertussis vaccine; *HCT,* hematopoietic cell transplantation.
*Vaccinations are deferred in patients with chronic graft-versus-host disease (GVHD) until discontinuation of immunosuppression.
†A minimum of 1-month interval between doses is suggested.
‡Following the primary series of three pneumococcal conjugate vaccine (PCV) doses, a dose of the 23-valent pneumococcal polysaccharide vaccine (PPSV23) to broaden the immune response might be given. For patients with chronic GVHD who are likely to respond poorly to PPSV23, a fourth dose of the PCV should be considered instead of PPSV23.
§DTaP is preferred; however, tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine (Tdap) can be used if DTaP is not available.
‖For children younger than 9 years of age, two doses are recommended yearly between transplant and 9 years of age.
¶Not recommended less than 24 months post-HCT, in patients with active GVHD, and in patients on immune suppression. In children, two doses of measles, mumps, and rubella virus vaccine live are favored. Lower viral-dose vaccines (varicella vaccine live [Varivax], not zoster vaccine live [Zostavax]) may be preferred as potentially safer.

the most important mechanism resulting in CMV disease.[30-32] Nearly all CMV infections (<5%) in seronegative recipients are the result of exogenous exposure (primary CMV infection), either from a seropositive stem cell donor or from cellular blood products from CMV-seropositive donors. The possibility of false-negative serology before HCT should also be considered in patients with early CMV reactivation. CMV infection and especially end-organ disease is also more frequent following allogeneic HCT, with CMV infections occurring in less than 5% of autograft recipients.[33,34] However, autologous HCT recipients who have previously received T-cell suppressive therapies (e.g., fludarabine, alemtuzumab) can be at high risk for CMV infection. Among patients undergoing allogeneic transplantation, the risk may be greater with URD compared to related donors.[35] Although the prevalence of donor seropositivity is nearly zero in UCB grafts, the risk for posttransplant CMV infection may be similar because recipient CMV status is still the predominant risk factor for infection, although the CMV-naïve UCB graft confers no latent protective immunity against CMV.[21,22] Other factors that delay immune reconstitution may also increase the risk for CMV infection, including older recipient age, increasing donor-recipient HLA mismatch, acute and chronic GVHD, and need for prolonged immunosuppression, especially with high-dose corticosteroids.[28,33,36-38] CMV reactivation posttransplantation may also be modulated by natural killer (NK) cell activity through donor activating killer immunoglobulin-like receptors.[39]

Clinical Presentation and Diagnosis

The most common manifestation of CMV infection is asymptomatic reactivation noted by screening antigenemia or DNA PCR testing. CMV organ infection and disease are most often pneumonia and enteritis. CMV is the most common specific cause of interstitial pneumonitis and is responsible for up to 50% of all cases.[40] Infection at other sites such as retinitis, hepatitis, and central nervous system disease are less common and are usually seen in late-onset or

persisting CMV infection.[28] Indirect effects of CMV infection may include increased risks for graft rejection and bacterial and fungal superinfection.[28,30] The presence of posttransplant CMV viremia is a strong predictor of subsequent clinical disease.[38,41,42] CMV pneumonia develops in 60% of patients with untreated asymptomatic viremia, and treatment of viremia can reduce the incidence of CMV pneumonia to less than 5%.[41,43-45] Although autologous HCT recipients have a lower risk for developing CMV infection, the severity of infection (e.g., pneumonia), if it develops, is similar to that observed in recipients of allogeneic transplantation.

The diagnosis of CMV can be made either by demonstration of characteristic cytopathic effects in tissue culture or by the use of more-sensitive molecular methods that detect viral protein or DNA. Commonly used molecular assays include CMV DNA detection methods, and the pp65 antigenemia assay. Detection of the CMV pp65 antigen in leukocytes has been a commonly used method for CMV surveillance after HCT but is ineffective during early post-HCT leukopenia. However, direct detection of CMV DNA either by PCR or DNA hybrid capture assay is the most sensitive method to detect CMV.[46-49] Furthermore, plasma CMV DNA PCR, though not as sensitive as whole blood PCR, can be a valuable tool to monitor CMV during periods of neutropenia when CMV antigenemia testing is unreliable. In addition, quantitative real-time PCR assays allow estimation of viral load, which can assist in determining need for therapy and risk for disease progression and in monitoring response among patients on anti-CMV treatment. Viral cultures of urine, saliva, blood, or bronchioalveolar lavage (BAL), using either rapid shell-vial or routine culture techniques, have limited clinical utility because they are less sensitive than antigen or DNA detection techniques and take much longer to report. Shell-vial cultures of CMV from BAL fluid are less specific for CMV pneumonia and can be positive in asymptomatic seropositive patients without pneumonia who are shedding CMV in oral or respiratory secretions.[50] Despite this lack of specificity, even in asymptomatic people, finding CMV in BAL fluid is a strong predictor for the development of subsequent CMV pneumonia, and such patients should be treated.

Prevention and Treatment

For seronegative recipients, the use of seronegative donors and CMV-safe blood products is the mainstay of prevention of CMV disease (see box on Approach to Prevention and Treatment of Cytomegalovirus Infection). For high-risk patients (seropositive recipients or seropositive donors of seronegative recipients), two general strategies can be used, both of which have been effective in reducing early CMV infection rates to less than 10%.[28,44,45,51-53] The first is the "preemptive" approach, which involves prompt treatment of early CMV viremia with ganciclovir, valganciclovir, or foscarnet before it can lead to clinical disease. The second is the "general prophylaxis" approach, in which all at-risk patients are treated with antiviral prophylaxis. The former approach requires availability and frequent scheduled use of reliable and rapid early diagnostic tests. The latter approach can reduce the rate of early CMV infection but does not affect mortality or the risk for late CMV infection and is associated with a higher incidence of ganciclovir-induced myelosuppression.[45,51,54] Both approaches require aggressive surveillance to allow prompt detection of infection. High-dose acyclovir or valacyclovir, although not as effective as ganciclovir, also reduces the incidence of CMV viremia, but continued surveillance for CMV is still required with prompt initiation of preemptive therapy with ganciclovir or foscarnet when viremia develops.[55-58] Unlike ganciclovir, which has to be administered intravenously, its prodrug valganciclovir, has excellent oral bioavailability and is often used for prophylaxis and preemptive therapy of CMV infection among HCT recipients.[59-62] Because autologous HCT recipients have a lower risk for CMV disease, the preemptive approach to preventing CMV infection is usually sufficient. Surveillance for CMV is continued weekly until at least day 100 posttransplant for high-risk patients and is continued longer in patients with chronic GVHD on high-dose immunosuppression.

Approach to Prevention and Treatment of Cytomegalovirus Infection

Prevention

1. Seronegative recipient with seronegative donor (allogeneic and autologous): Transfuse only cytomegalovirus (CMV)-safe blood products. Leukocyte depletion by filtration and blood from CMV-seronegative donors are clinically equivalent alternatives.
2. Seronegative recipient with seropositive donor (allogeneic): Deliver only CMV-safe blood products (seronegative or leukocyte depleted), but administer chemoprophylaxis as well to prevent reactivation of donor-derived endogenous virus.
3. Seropositive recipients: Prophylaxis with acyclovir appears to be somewhat useful. Use of immunoglobulin may be beneficial. There is no proven role for seronegative blood products. Ganciclovir is highly effective when given prophylactically but is myelosuppressive. Patients who must interrupt the course of ganciclovir because of leukopenia are at risk for development of CMV pneumonia. Ganciclovir (or valganciclovir) is the current best prophylaxis in high-risk patients but is not indicated for autologous recipients. Intensive surveillance and early preemptive therapy may be equivalently effective.
4. All patients need periodic (weekly) monitoring for CMV antigenemia or CMV deoxyribonucleic acid (DNA) polymerase chain reaction for 8 to 12 weeks posttransplantation. Longer-duration (beyond 12 weeks) surveillance is appropriate for allograft recipients, especially those with graft-versus-host disease.

Treatment

1. Asymptomatic infections (allogeneic and autologous): Ganciclovir or valganciclovir treatment of asymptomatic infection detected in blood or bronchioalveolar lavage (BAL), by either molecular detection or antigenic methods, is recommended to prevent the development of CMV pneumonia. Intensive induction treatment (2 weeks) followed by a maintenance phase of 5 days/wk therapy for an additional 4 to 8 weeks is necessary.
2. CMV pneumonia: Ganciclovir in combination with immunoglobulin is recommended. This should be instituted promptly. Once the disease has progressed to cause respiratory failure and ventilator dependence, survival is limited.

No Treatment

1. Empiric CMV therapy for interstitial pneumonitis is not indicated in seronegative recipients with seronegative graft and blood donors. Diagnostic evidence of CMV infection should be obtained.
2. Empiric CMV therapy for interstitial pneumonitis is also not indicated in patients whose BAL is negative for CMV by direct staining and molecular testing. However, BAL CMV studies have a small (<5%) false-negative rate, and close follow-up and monitoring is still required.
3. Asymptomatic CMV viruria does not require therapy but does need close follow-up and serial blood viral testing for surveillance of systemic disease.

CMV disease, especially pneumonia, must be diagnosed and treated promptly because it remains associated with very high rates of mortality.[33] The combined use of ganciclovir and immunoglobulin has been the most successful treatment for CMV pneumonia, with resolution in 50% to 75% of non–ventilator dependent patients.[33,63,64] Prolonged therapy (>2 months) with the combination is indicated because shorter treatment regimens have been associated with

recurrence of CMV pneumonia. Foscarnet can be effective in clinical settings in which ganciclovir fails or is associated with excess toxicity, usually myelosuppression.[65] Although treatment is generally similar, with ganciclovir or foscarnet plus immunoglobulin, CMV enteritis, hepatitis, and retinitis are variably responsive.[28,66] The efficacy of valganciclovir for treatment of CMV organ disease is being investigated. Adoptive cellular therapies (using approaches to enhance NK or infuse CMV-targeted T cells) are also being explored.[67-69] Although rare, CMV antiviral resistance can occur, and ganciclovir or foscarnet can be used as alternative drugs for second-line therapy. Cidofovir can be considered when disease progresses despite treatment with ganciclovir and foscarnet, and a liposomal formulation with good oral bioavailability is being studied.

Other Viral Infections

Primary and reactivation infections of other herpesviruses can occur after transplantation. Herpes simplex virus (HSV) infection is uncommon with the use of acyclovir or valacyclovir prophylaxis in serologically positive patients. Acyclovir-resistant HSV infection can occur in patients given low-dose prophylaxis or intermittent treatment and recipients of T cell–depleted grafts[70]; Foscarnet is the drug of choice for resistant disease with cidofovir reserved as an alternative agent. VZV reactivation can occur in 30% to 50% of HCT recipients with previous exposure to VZV and can be effectively prevented or delayed by acyclovir prophylaxis. Acyclovir prophylaxis has been suggested for the first year after transplantation for VZV-seropositive autologous and allogeneic HCT recipients; patients with chronic GVHD need to continue prophylaxis for the duration of their immunosuppression.[1,71]

HCT recipients can be prone to community-acquired respiratory viral (CRV) infections with influenza, parainfluenza, and respiratory syncytial virus (RSV). Because upper respiratory infections can progress to more-serious lower respiratory infections and certain CRVs can be treated, appropriate diagnostic testing (e.g., nasopharyngeal swabs) should be considered to identify the virus if possible. Zanamivir or oseltamivir can be used for chemoprophylaxis and treatment of influenza. Aerosolized ribavirin can be considered in patients with RSV infection, especially if they are early posttransplantation or have lower respiratory tract involvement.

Adenovirus infections can occasionally occur after allogeneic HCT, especially among recipients of T cell–depleted grafts and in patients with GVHD.[72] Human polyomavirus type I, also known as BK virus, can cause hemorrhagic cystitis in the early posttransplant period.[73] Urine PCR can identify BK virus and distinguish it from hemorrhagic cystitis caused by other infections (e.g., adenovirus) and urotoxic agents (e.g., cyclophosphamide). Quinolone antibiotics suppress BK virus replication in vivo and in vitro and may have a role as prophylaxis in patients at high risk for hemorrhagic cystits.[74] Intravesical or intravenous cidofovir has been used for the treatment of BK virus hemorrhagic cystitis.[11]

Fungal Infections

Invasive fungal infections are among the leading causes of mortality in HCT recipients. The vast majority of fungal infections in this setting are caused by yeasts (*Candida* spp.) or molds (*Aspergillus* spp.).

Candida Infections

Candida albicans has been the leading cause of yeast infections in HCT recipients, but the current widespread use of azole prophylaxis in the early transplant period has led to the emergence of a variety of non-*albicans* species, such as *Candida tropicalis, Candida krusei,* and *Candida glabrata,* as important pathogens.[75] These yeasts are normal inhabitants of the skin and the oral and gastrointestinal mucosa. Breakdown of these mucosal surfaces due to radiation and chemotherapy, compounded by neutropenia in the preengraftment period, can greatly increase the risk for invasion and systemic infections. Presence of indwelling central venous catheters and alteration of normal surface flora due to antibiotics are additional risk factors for *Candida* infections.[3,76]

Clinical manifestations can range from localized mucocutaneous to disseminated deep-tissue infection. A high index of suspicion is needed for the diagnosis of *Candida* infections, especially in patients with persistent febrile neutropenia, because blood cultures are usually not very sensitive for isolation and identification of *Candida* spp. Oral and esophageal candidiasis frequently occurs in the early posttransplant period and should be treated aggressively because they can serve as portals for subsequent systemic infection. Venous catheter infections can be difficult to eradicate with antifungal agents alone and necessitate removal of the central line. Patients with candidemia are also at risk for endovascular infections such as endocarditis and thrombophlebitis. Hepatosplenic candidiasis is the most common manifestation of disseminated candidiasis but is increasingly rare with widespread use of effective anti-*Candida* azoles and echinocandins. Specific signs or symptoms related to organ involvement may be absent, and the diagnosis frequently has to be made by abdominal CT scan imaging.

Prophylaxis with fluconazole is recommended in the preengraftment and early postengraftment period, especially among allogeneic HCT recipients.[1,77,78] In patients who are at high risk for mold infections, caspofungin, micafungin, voriconazole, or posaconazole can be considered because they have antimold activity.[79-83] *C. krusei* and *C. glabrata* are intrinsically resistant to fluconazole and other agents (e.g., posaconazole, voriconazole, or micafungin) should be preferred for prophylaxis in patients colonized with fluconazole-resistant *Candida* species. Itraconazole is another active agent, but its use is limited by its tolerability, absorption, and toxicities. Cross-resistance to azoles can occur among *Candida* species. Antifungal agents for treatment of suspected or known invasive candidiasis include voriconazole or posaconazole, echinocandins, or an amphotericin formulation, especially when infection occurs in the setting of ongoing fluconazole prophylaxis.[78]

Aspergillus Infections

Most mold infections in HCT recipients are due to *Aspergillus fumigatus, Aspergillus flavus,* and *Aspergillus niger,* which gain entry through breakdown of mucosal surfaces or through the nasal passages and respiratory tract. *Aspergillus* infections can occur early after HCT (during the neutropenic phase) or later, especially complicating the immunosuppression associated with acute or chronic GVHD.[84,85] Risk factors for *Aspergillus* infections include allogeneic (more than autologous) HCT, prolonged neutropenia, and GVHD.[18,84-86] Transplantation for diseases that cause extended neutropenia pretransplantation (e.g., chronic granulomatous disease, aplastic anemia, and myelodysplastic syndrome [MDS]) also increases the risk. Prior history of *Aspergillus* infection has also been observed to be a risk factor for reactivation after HCT.[87]

Aspergillus occurring in the posttransplant setting can be difficult to diagnose premortem. Hence a high index of suspicion and an aggressive approach are required to establish its diagnosis and initiate therapy. Because the nasal passages and tracheobronchial tree are the most common portals of entry for *Aspergillus* spp., these two sites are also the most common sites of infection. Sinusitis is frequently symptomatic, and more advanced disease can be associated with erosion and necrosis of surrounding structures. Pulmonary manifestations typically include nodular infiltrates, usually distributed along the lung periphery, with pleuritic pain or cough as an initial symptom. Frank consolidation (with a halo sign on CT scan) or cavitary lesions can be seen in more advanced stages of pulmonary involvement. *Aspergillus* has angioinvasive properties and can present with hemoptysis or with intravascular dissemination to the skin or brain.

Blood cultures have a very low sensitivity in detecting *Aspergillus,* and diagnosis has to rely on demonstration of typical fungal

morphology on culture or histopathology or on tests to detect fungal components or nucleic acids. Nasal and bronchial washings for *Aspergillus* also may not be sensitive, and lung biopsy may be required to obtain a definitive diagnosis.[88] The galactomannan assay is an enzyme-linked immunosorbent assay to detect the *Aspergillus* cell wall glycoprotein; it has a high specificity but low sensitivity for diagnosing invasive aspergillosis and has not been reproducible in well-designed trials.[89-91] Molecular methods for diagnosis, including PCR for *Aspergillus* DNA, are also undergoing development.[92] More-invasive evaluations (e.g., fine-needle aspiration or biopsy) are often needed to confirm the presence of *Aspergillus* in suspicious lesions identified on clinical examination or imaging studies.[93]

The use of high-efficiency air filters has reduced the nosocomial acquisition of *Aspergillus,* at least during the early neutropenic phase when isolation measures are used.[75] The optimal pharmacologic strategy for primary prophylaxis against aspergillosis in HCT recipients is not well defined.[94] Posaconazole has been shown to be effective for prophylaxis in HCT recipients with GVHD.[95] Itraconazole is also effective, but side effects limit its use.[80] A large randomized trial showed no difference in fungal-free survival between voriconazole and fluconazole in HCT recipients at low risk for disease progression or early HCT mortality, although there was a trend toward fewer *Aspergillus* infections and less empiric antifungal use in voriconazole recipients.[83] Inhaled or low-dose intravenous amphotericin has not been shown to be effective for primary prophylaxis.[94,96,97] In patients with a previous history of invasive aspergillosis, secondary prophylaxis with a mold-specific azole (e.g., oral voriconazole or posaconazole) or parenteral echinocandins or amphotericin preparation is recommended, possibly for the duration of intensive immunosuppression.[94] Therapy with a mold-specific azole, an echinocandin, or an amphotericin preparation should be initiated in patients with invasive aspergillosis or in high-risk patients with persistent febrile neutropenia. Azoles and echinocandins have a more favorable side-effect profile compared to amphotericin formulations. Patients with disease progressing on a single antimold drug might need combination therapy with two antimold agents. The role of adjunctive measures such as cytokine growth factors, immunoglobulin infusion, or granulocyte transfusion remains undefined.

EARLY NONINFECTIOUS COMPLICATIONS

High-dose chemotherapy and radiation regimens are used before transplantation for their antineoplastic and immunosuppressive effects. However, these treatments can damage host tissue, resulting in significant morbidity.[98] Early HCT-associated complications can frequently simulate infections or be compounded by concurrent infections. In addition, because epithelial tissue repair may be delayed by ongoing neutropenia and local microinvasive infection, delay in hematopoietic engraftment can exaggerate and prolong these toxicities.

Graft Failure

Failure to establish hematologic engraftment (primary graft failure) and loss of an established graft (late graft failure) are serious complications of both autologous and allogeneic HCT. Delayed or poor graft function can exaggerate and prolong the risks of infection and can increase the risk for peritransplant mortality. Failure to engraft can occur if insufficient hematopoietic progenitors are infused. A minimum of approximately 2×10^4 colony-forming cells from marrow per kilogram recipient weight are needed to establish autologous engraftment. This is accomplished by infusing approximately 1×10^8 autologous marrow mononuclear cells per kilogram. Most investigators recommend infusion of a minimum of at least 2×10^8 mononuclear cells per kilogram to ensure establishment of an allogeneic graft. UCB-derived hematopoietic grafts can engraft with a lower number of cells.[99] Stem cells and progenitors can be damaged by cryopreservation or by ex vivo purging, and additional cells are required if intensive purging, especially with alkylators, is performed, though currently this approach to autograft preparation is uncommon. Selection of $CD34^+$ cells as a technique for tumor cell depletion does not compromise engraftment, unless the quantitative cell losses through selection are excessive.

The use of hematopoietic stem cells and progenitors harvested from the blood by apheresis instead of the bone marrow has become widely prevalent, both for autologous and allogeneic HCT. Autologous blood hematopoietic cell grafts are collected after mobilization of marrow-derived progenitors into the blood by cytokine (G-CSF or GM-CSF) therapy or during recovery from myelosuppressive chemotherapy, often in combination with growth factors.[100-103] Progenitor content of blood or marrow grafts is assayed by quantitation of mononuclear cells expressing the hematopoietic progenitor–associated surface marker CD34. Peripheral graft mobilization can be further enriched by the use of plerixafor, an inhibitor of CXCR4 that releases cells from the marrow.[104,105] Allogeneic grafts are mobilized from healthy donors using growth factors alone, nearly exclusively using G-CSF, though early experience with plerixafor has been reported.[106,107]

Graft failure is uncommon if 2×10^6 $CD34^+$ cells/kg or more are collected, cryopreserved, and later infused as an autologous graft.[101,102] The minimum CD34 content for an allogeneic graft is less well defined, but more than 5×10^6 $CD34^+$ cells/kg is frequently cited as a target collection for a sibling donor allograft.[108-110] Mobilized peripheral blood–derived stem cells yield satisfactory and more rapid trilineage hematopoietic recovery than grafts from marrow-derived cells.[110-113] Similar to marrow grafting, late graft failure is possible, but unlikely (<5%) after transplantation using peripheral blood–derived stem cells. Infusion of a sufficient graft cell dose (nucleated or $CD34^+$ cells) may be the most important controllable factor to limit the risk for graft failure.

Recipient myelofibrosis or splenomegaly can interfere with engraftment. Splenomegaly can delay hematologic recovery, presumably because both progenitors and mature blood cells are sequestered in the spleen.[114] The presence of moderate to severe myelofibrosis also delays engraftment, perhaps because of faulty homing of stem cells in the marrow microenvironment.[115,116]

Posttransplantation therapy can jeopardize engraftment. Graft failure or poor graft function has been associated with use of methotrexate, ATG, acyclovir, ganciclovir, trimethoprim-sulfamethoxazole (TMP-SMX), and mycophenolate mofetil (MMF). Posttransplant complications such as CMV, human herpesvirus-6 or fungal infections, and acute and chronic GVHD can also compromise successful engraftment.

Allogeneic HCT, especially using unrelated or mismatched donors, poses unique engraftment problems. Transplants between siblings completely matched at HLA-A, HLA-B, and HLA-DR loci are rarely (1% to 3%) associated with graft failure; however, the probability of graft failure in the related-donor transplantation setting increases to near 10% with greater degrees of donor-recipient HLA incompatibility.[117-120] The problem is frequent (5% to 15%) in the URD setting, where primary or secondary graft failure may occur even after transplantation from donors well matched at the HLA-A, HLA-B, HLA-C, and HLA-DR loci.[119-122] In some cases, failure of URD stem cells to engraft may result from reactivity against other important histocompatibility determinants, including HLA-C.[123] Early failure of an allogeneic graft can be accompanied by emergence of cytotoxic T lymphocytes of host origin, presumably representing immune-mediated graft rejection.[124,125] T-lymphocyte depletion of donor marrow performed as GVHD prophylaxis can also adversely affect engraftment, even from matched sibling donors.[118,126] Ex vivo marrow manipulation can deplete stem cells. T-cell depletion can also render the graft immunoincompetent and functionally less capable of preventing graft rejection.

Compared to related or URD allografts, time to neutrophil recovery is significantly delayed in patients receiving UCB grafts. In addition, the overall incidence of graft failure is somewhat greater.[127-130] The most critical determinants of engraftment following UCB

transplantation are both HLA matching and cell dose, and units with a total nucleated cell dose of at least 2.5×10^7 cells/kg or more have a greater probability of successful engraftment.[129-131] Because each UCB unit has a limited number of hematopoietic progenitor cells, methods to overcome this limitation of cell dose are being investigated. These include transplantation using multiple UCB units, ex vivo expansion to increase the number of progenitor cells, and intra–bone marrow injection of the graft. Increasing overall cell dose with transplantation of two UCB units can lead to successful engraftment, especially in adults.[99,132-134]

The use of recombinant G-CSF or GM-CSF, which stimulates myelopoiesis, has improved the treatment of graft failure.[135] Improvement in myelopoiesis can be seen in 50% to 60% of patients with poor graft function within 14 to 21 days after initiation of growth factor therapy. Myeloid growth factor therapy can increase peripheral blood leukocyte recovery but has little effect on platelet reconstitution. Recombinant human thrombopoietin receptor agonists are now available, although their efficacy and safety profile in HCT recipients is uncertain and parallel experience in treating chemotherapy-induced thrombocytopenia suggests that they will be ineffective. Limited experience suggests the value of recombinant erythropoietin in reducing red blood cell transfusion needs.[136]

A second stem cell infusion can be useful if graft failure occurs. In the case of a failed autograft, infusion of previously harvested and frozen marrow or blood cells frequently reestablishes functional hematopoiesis and hematologic improvement. In the case of graft failure after related-donor transplantation, a second infusion of donor marrow or cytokine-stimulated peripheral blood stem cells may allow successful engraftment.[137] Sometimes, due to the presumption of immune-mediated rejection, reconditioning with reduced doses of cytotoxic agents or further immunosuppression with ATG, corticosteroids, or cyclosporine is used to prepare the recipient for a second infusion.

The treatment of graft failure after URD transplantation poses special problems. Unrelated donors may not be available for a second marrow harvest or blood stem cell apheresis. In experimental settings in which graft failure risks are high, it may be prudent to store autologous stem cells from patients undergoing URD transplantation, though this is rarely done. The original donor is unavailable in recipients of unrelated UCB grafts and the only treatment option for graft failure in this setting is a second transplant using cells from a different UCB or volunteer adult donor (related or unrelated) second allograft, or reinfusion of autologous back-up cells if available. Because of variability in the circumstances and donor options available, there are few clear data on the outcomes of second allografts in these situations.[138-140]

Sinusoidal Obstruction Syndrome

Sinusoidal obstruction syndrome (SOS), also known as hepatic veno-occlusive disease (VOD), is a serious liver disorder characterized by jaundice, ascites, fluid retention, and hepatomegaly that complicates up to 5% to 50% of HCTs. The differing incidence is based upon stringency of the definition of the clinical diagnosis (see box on Sinusoidal Obstruction Syndrome).[141-144] The primary initiating event is thought to be portal hypertension due to obstruction of hepatic sinusoids and venules, which secondarily leads to damage to surrounding centrilobular hepatocytes.[145-147] Chemotherapy and total body irradiation (TBI) used in pretransplant conditioning regimens produce sinusoidal endothelial injury. Subsequent deposition of fibronectin and factor VIII/von Willebrand factor at the site of damaged endothelium can lead to activation of the coagulation system and subsequent sinusoidal obstruction.[148] Such changes are often associated with depressed plasma protein C levels and other signs of procoagulant activity, including lower antithrombin III levels and elevated factor VIII and fibrinogen levels.[149-153] Cytokines such as tumor necrosis factor (TNF)-α and alterations in the levels of nitric oxide and matrix metalloproteinases may also have a role in its pathogenesis.[154-157]

Sinusoidal Obstruction Syndrome

Diagnostic Criteria for Sinusoidal Obstruction Syndrome

Bilirubin level of 2 mg/dL or above before day 21 after hematopoietic cell transplantation (HCT) and at least two of the following: (1) hepatomegaly or right upper quadrant pain, (2) ascites, or (3) weight gain of more than 5% over baseline.

Sinusoidal obstruction syndrome (SOS) is a clinical diagnosis; liver ultrasound with Doppler studies or liver biopsy can support or confirm the diagnosis.

Risk Factors

Pretransplant Factors

- Prior hepatic inflammatory disease (e.g., chronic hepatitis B or C, nonalcoholic steatohepatitis, alcoholic hepatitis)
- Prior hepatic fibrotic disease (e.g., cirrhosis)
- Extensive pre-HCT chemotherapy
- Prior exposure to gemtuzumab ozogamicin
- Prior liver irradiation

Transplant-Related Factors

- Conditioning regimen (e.g., myeloablative total body irradiation or busulfan-based regimens)
- Exposure to other agents (e.g., sirolimus, itraconazole)

Prognostic Factors

Adverse prognostic factors include development of multiorgan failure, rapid increase in weight, and rapid increase in bilirubin level.

Treatment

More than 70% of patients will recover spontaneously from SOS with supportive care. However, mortality rates are over 80% for patients with severe SOS. Treatment options, especially for patients with more severe SOS, include the following:

Pharmacologic

- Ursodeoxycholic acid (prophylaxis)
- Defibrotide (investigational—prophylaxis and treatment)
- Low-dose heparin and low-molecular-weight heparin (prophylaxis)
- Tissue plasminogen activator (investigational—prophylaxis and treatment)
- Antithrombin III (investigational—prophylaxis and treatment)

Nonpharmacologic

- Supportive care with management of multiorgan failure
- Transjugular intrahepatic portosystemic shunt (TIPS)
- Liver transplantation

Risk factors associated with the development of SOS include history of pretransplant hepatitis or liver injury, intensive preparative regimens, increased TBI dose and dose rate, and increased busulfan dose.[141-144,147,158-161] SOS may also be more frequent after mismatched related or URD transplantation.[142-144] Prior therapy with gemtuzumab ozogamicin also increases the risk for posttransplant SOS.[162] Sirolimus has also been shown to increase the risk for SOS after myeloablative allogeneic HCT, particularly using busulfan-based regimens.[163]

Signs of SOS usually occur within 1 month after hematopoietic graft infusion but may be recognized much sooner, even during administration of the preparative regimen. Clinical evidence of VOD includes hyperbilirubinemia, tender hepatomegaly, ascites, and

weight gain.[141,143,147] More advanced stages can be associated with encephalopathy along with renal, pulmonary, and multiorgan failure. The diagnosis of SOS is primarily based on clinical criteria that include presence of jaundice with either hepatomegaly, weight gain, and/or ascites within 2 to 3 weeks of stem cell infusion.[141,164] However, other causes of hyperbilirubinemia and weight gain early after transplantation (e.g., drugs, hepatitis, capillary leak, cardiac failure, and salt and colloid overloading) can complicate the differential diagnosis, particularly for milder or less abrupt presentations of these symptoms. Percutaneous or transabdominal needle biopsy of the liver is hazardous in severely thrombocytopenic transplant recipients and should be avoided. Transvenous biopsies may provide sufficient histologic material for diagnosis and may allow determination of hepatic wedge pressure product (greater than 10 mm is associated with SOS) but may be associated with hemorrhagic complications as well.[165] Ultrasonographic Doppler flow studies demonstrating reversal of portal flow or a higher portal vein resistive index have been suggested as a noninvasive means of confirming the diagnosis, but their validity has recently been questioned.[166-168] SOS can be graded from mild to severe depending on the degree of hyperbilirubinemia and weight gain, and severe SOS is almost universally fatal within several weeks of onset.[143,169]

Effective methods for prevention and treatment of SOS have not been defined. Limited understanding of the cellular and microvascular pathophysiology of SOS has confounded development of more rational approaches to its prevention and treatment. Possible approaches include preventive therapy with low-dose heparin,[170-172] prostaglandin E,[173] pentoxifylline (a TNF-α blocking agent),[174,175] or ursodiol,[176,177] although none has proved effective in carefully performed prospective trials. Recombinant tissue plasminogen factor has been used successfully to treat established SOS; however, thrombolytics are associated with substantially increased risk for hemorrhage.[178-181] Transjugular intrahepatic portosystemic shunts have also been used with some success.[182,183] Early experience with defibrotide, a single-stranded polyribonucleotide with fibrinolytic, antithrombotic, and antiischemic properties, has been favorable with 30% to 40% of patients with severe SOS achieving complete resolution and improvement in survival.[184-187] Its efficacy in the prophylaxis and management of severe SOS is currently being investigated in larger clinical trials.

Interstitial Pneumonitis

Interstitial pneumonitis is a common and frequently fatal complication, affecting up to 35% of allogeneic transplant recipients, although advances in supportive care have led to substantial reductions in this risk.[188,189] Interstitial pneumonitis is notably less common after autografting.[190] It is characterized by diffuse, nonbacterial interstitial inflammation accompanied by hypoxemia, dyspnea, and nonproductive cough, sometimes with fever. Risk factors associated with the development of interstitial pneumonitis include use of methotrexate for GVHD prophylaxis, older age at transplant, severe GVHD, interval from diagnosis of hematologic disease to HCT of 6 months or greater, poor pretransplant performance status, and use of higher TBI dose rate (>4 cGy/min).[188,189] Remarkably, in one study, the reported risk for interstitial pneumonitis was 8% when none of these risk factors was present, compared to 94% when all six factors were present.[188] It has been hypothesized that URD transplantation is more immunosuppressive and thus associated with more severe opportunistic infections and greater risk for interstitial pneumonitis, but this has not been rigorously investigated.

The course of interstitial pneumonitis is often catastrophic, manifesting with rapidly progressive tachypnea, hypoxemia, and hemodynamic compromise. Therefore therapeutic intervention most frequently occurs before the return of definitive results of diagnostic tests and must be initiated based on the assessment of clinical risk factors and the underlying clinical setting (see box on Approach to Interstitial Pneumonitis).

Infectious Causes of Interstitial Pneumonitis

Infections are the most common cause of interstitial pneumonitis in HCT recipients. CMV and *Aspergillus* are the most common infections associated with interstitial pneumonitis and have been discussed earlier in this chapter. Other important though relatively uncommon infections to consider are *Pneumocystis jiroveci* and RSV and similar respiratory viruses.

Pneumonitis caused by *Pneumocystis* has a typical bilateral distribution with a "butterfly" pattern on chest radiograph and prominent hypoxemia and rarely causes pleural effusions.[191] The previously reported 5% to 15% risk for *Pneumocystis* pneumonia has been largely eliminated by routine use of prophylaxis with TMP-SMX (first choice), dapsone, or inhaled pentamidine.[192,193] Prophylaxis with TMP-SMX virtually eliminates *Pneumocystis* pneumonia from the differential diagnosis, but only if patient compliance with therapy is certain. Diagnosis requires cytologic evaluation of silver-stained preparations of BAL cells or sputum, although transbronchial lung biopsy may slightly increase the diagnostic yield of a bronchoscopic examination. *Pneumocystis* pneumonia is effectively treated with high-dose TMP-SMX or parenteral pentamidine. Prophylaxis against *Pneumocystis* pneumonia should be continued through the period of immunosuppression (6 months to 1 year posttransplantation) and for the duration of any therapy for chronic GVHD.

RSV is a potentially fatal cause of interstitial pneumonitis and typically occurs in the fall and winter months.[194] RSV should be suspected if the patient presents a history of rhinorrhea and if RSV has been frequently recognized in the community or in the hospital. Diagnosis can be made by rapid antigen testing on nasal washings or BAL specimens. Because of the possibility of horizontal transmission, patients with RSV should be isolated. Inhaled ribavirin is used for treatment of RSV-associated pneumonia.[195] Other community-acquired viruses, such as parainfluenza or influenza, can also cause interstitial pneumonitis in the transplant recipient. Their presentation is clinically indistinguishable from RSV, though parainfluenza pneumonitis is not seasonal and may be seen year-round. Yearly influenza vaccination for HCT recipients and especially their household contacts may be effective in reducing risks for this infection.

Noninfectious Causes of Interstitial Pneumonitis

Idiopathic Interstitial Pneumonitis

Idiopathic interstitial pneumonitis is a diagnosis of exclusion based on typical findings and ruling out infectious causes. Its timing is somewhat earlier than other causes of interstitial pneumonitis, typically occurring within the first 2 to 7 weeks after HCT.[40,196,197] The recognized risk factors for idiopathic interstitial pneumonitis include older age at transplant, extensive pretransplant chemotherapy, high-dose cyclophosphamide, TBI (higher total dose and dose rate), blood transfusions, administration of methotrexate, and GVHD.[198-201]

The observation that idiopathic interstitial pneumonitis is as frequent among syngeneic as among allogeneic recipients and has an equally high incidence in T cell–depleted grafts suggests that immunosuppression is less of a risk factor for idiopathic interstitial pneumonitis than it is for infectious interstitial pneumonitis.[202,203] Clinical observations support a toxic cause for idiopathic interstitial pneumonitis and radiation-induced lung damage appears to be the major contributor, especially the use of high-dose TBI.[204,205] Effective therapy has not been established, although high-dose corticosteroids are often administered. Inflammatory cytokines, including interleukin(IL)-1 and TNF-α, have been implicated in lung injury.[206,207] Etanercept, a TNF-α–binding protein has been reported to improve lung function in patients with idiopathic interstitial pneumonitis, particularly if administered before the need for mechanical ventilation. Its use is currently undergoing evaluation in clinical trials.[208,209]

Approach to Interstitial Pneumonitis

The presentation of interstitial pneumonitis after hematopoietic cell transplantation (HCT) should be considered an urgent medical situation, and empiric broad-spectrum therapy must be initiated early. The choice of therapy is influenced by the following:

1. Timing: Within the first 3 weeks after HCT, interstitial pneumonitis is more likely to be idiopathic (including diffuse alveolar hemorrhage) or fungal than due to cytomegalovirus (CMV) infection. Beyond 6 weeks, idiopathic pneumonitis is unusual, and the cause is more likely infectious. *Pneumocystis jiroveci* pneumonia is rare beyond 1 year after transplantation except in patients with ongoing chronic graft-versus-host disease (GVHD). Respiratory syncytial virus (RSV) infections are seasonal (fall and winter), and community outbreaks can be prevalent. Influenza is also seasonal, whereas parainfluenza can occur year-round.
2. CMV serology and prophylaxis: If a seronegative recipient has received a seronegative graft and noninfective (seronegative or leukocyte-depleted) blood, CMV pneumonia is unusual. Seropositive recipients are at higher risk, although with ganciclovir or other antiviral prophylaxis, the risk is markedly reduced. Other prophylactic regimens for CMV, such as acyclovir or intravenous immunoglobulin, have still been associated with significant risk for serious CMV infection in the seropositive recipient. Serial negative testing for CMV antigenemia or deoxyribonucleic acid (DNA) polymerase chain reaction (PCR) makes CMV pneumonitis less likely.
3. Prolonged neutropenia: This factor is associated with infectious causes, particularly with fungal pneumonias.
4. Type of transplant: Diffuse alveolar hemorrhage is less frequently seen in patients undergoing autologous HCT. CMV pneumonia is unusual (2% to 3%) in autologous recipients, but it still has a high case fatality rate. All infectious causes are more common after allogeneic HCT. More-intensive conditioning regimens (e.g., higher total body irradiation, carmustine) are associated with more frequent pneumonitis.
5. Compliance and prophylaxis: A thorough assessment of what prophylaxis the patient has actually been receiving (e.g., trimethoprim-sulfamethoxazole, penicillin, CMV prophylaxis, transfusions outside the transplant center) is critical to assess risk.
6. Chest radiograph: The pattern and distribution of the infiltrate may narrow the differential diagnosis. Cardiac enlargement or pleural effusions may suggest pulmonary edema. A chest computed tomographic scan is useful, especially if nodularity, pleural involvement, or cavitary lesions (possibly fungal) are suspected.
7. Epidemiology: Identification of the causes of other recent cases can be most helpful with infections that are horizontally transmitted (e.g., RSV) or have common environmental risk factors (e.g., *Aspergillus* infection associated with construction).
8. Bronchoalveolar lavage (BAL): This can be extremely useful to establish a specific diagnosis or to exclude others. CMV rarely causes pneumonia without positive BAL findings (either direct staining of CMV-associated antigens in BAL cells or DNA PCR). BAL also usually detects RSV, *Pneumocystis jiroveci,* and other respiratory viruses, though not as rapidly, but is required to identify alveolar hemorrhage. It is less sensitive for diagnosis of fungal pneumonias.
9. Lung biopsy: Although this is the gold standard for definitive diagnosis of most of the possible causes of interstitial pneumonitis, it can often be avoided through the use of the clinical diagnostic measures listed. It may be necessary for the definitive diagnosis of fungal pneumonias, pulmonary changes associated with chronic GVHD (bronchiolitis obliterans), or idiopathic interstitial pneumonitis. Either bronchoscopic (transbronchial) biopsy, open surgical biopsy, or video-assisted thoracoscopic surgery can be performed. Transbronchial biopsies are insufficient for other than very diffuse processes and carry risks for bleeding and/or pneumothorax. The surgical approaches are more invasive, but more often definitive.
10. Ventilator therapy: Progressive respiratory failure after HCT is rarely reversible, especially in adults. Although aggressive diagnostic and therapeutic measures are essential, some centers offer patients and their families the option of foregoing mechanical ventilatory support if survival is not expected. Preliminary discussion of this possible complication in pretransplant patient counseling can facilitate decision making if respiratory failure does occur.

Diffuse Alveolar Hemorrhage

Alveolar hemorrhage is a clinical syndrome of acute onset of pulmonary infiltrates and hypoxemia with a progressively bloodier BAL on bronchoscopy.[210] Alveolar hemorrhage due to noninfectious causes has been called diffuse alveolar hemorrhage, but it is often difficult to distinguish it from infection-associated pulmonary hemorrhage, especially in the early posttransplant period.[211] The reported incidence of diffuse alveolar hemorrhage ranges from 2% to 5% in autologous and 5% to 10% in allogeneic HCT recipients.[210-214] Its pathogenesis is not known, but it most likely develops as result of a complex interaction of a variety of factors, including alveolar injury from radiation and chemotherapy, inflammatory damage due to neutrophils and cytokines, and underlying infections. Older age at transplant, use of allogeneic donor source, and GVHD are risk factors for this syndrome.[211,213] The risk is reportedly similar with nonmyeloablative and myeloablative conditioning regimens, but this has not been confirmed.[212] Onset typically occurs within the first 3 months of transplantation with dyspnea, and cough, although late-onset alveolar hemorrhage is not uncommon. Hemoptysis is usually absent, and bronchoscopy with BAL is required to confirm the diagnosis and to exclude infectious causes. This syndrome is very serious, and the majority of patients develop severe respiratory failure with mortality rates of more than 70%.[211,214] Hemorrhage occurring in the periengraftment period is associated with a better outcome compared to later-onset hemorrhage. Treatment includes correction of any coagulopathy and aggressive ventilatory support. High-dose corticosteroids have been used for its management, but their efficacy has not been clearly proven.[210,211,214] Small case series have reported the successful use of recombinant factor VIIa and aminocaproic acid, but their efficacy needs to be confirmed in clinical trials.[215-217] Cytokine antagonists (e.g., etanercept) might have a therapeutic role that is being investigated in clinical trials.

LATE NONINFECTIOUS COMPLICATIONS

Improvements in transplantation techniques and supportive care have led to an increasing number of long-term HCT survivors. Among HCT recipients who remain disease-free through 2 to 5 years posttransplantation, probability of survival over the next 10 to 20 years is more than 80%.[218-220] These survivors remain at risk for late transplant-associated complications, which can include organ-specific dysfunction, second cancers, infections due to ongoing immunodeficiency, and functional impairments and changes in quality of life (Table 110-5).[221-228] Guidelines for screening and prevention of late effects in HCT survivors have been published.[12] In addition, following general population guidelines for screening and prevention of cancers and chronic diseases and promoting a generally healthy lifestyle is recommended for all HCT survivors.

Table 110-5 Selected Late Complications of Hematopoietic Cell Transplantation

Complication	Risk Factors	Monitoring and Prevention
Endocrine		
Hypothyroidism	TBI/radiation	Periodic assessment of thyroid and gonadal function
Hypogonadism	Chronic GVHD	
Growth retardation	Chemotherapy	
Ocular		
Cataracts	TBI/radiation	Periodic eye examination
Keratoconjunctivitis sicca	Corticosteroids Chronic GVHD	
Oral		
Dental caries	TBI/radiation	Periodic dental assessment
Dry mouth	Chronic GVHD	
Cardiovascular		
Coronary artery disease	TBI/radiation	Periodic clinical evaluation
Cerebrovascular disease	Chemotherapy	Modification of risk factors
Respiratory		
Bronchiolitis obliterans	TBI/radiation	Periodic clinical evaluation
Interstitial pneumonitis	Chronic GVHD Infections	Smoking cessation
Hepatic		
Cirrhosis	Hepatitis B or C	Periodic liver function tests
Iron overload	Transfusions	Serum ferritin level
Renal		
Nephropathy	TBI/radiation	Periodic serum creatinine and urinalysis
	Chemotherapy Cyclosporine	Control hypertension
Skeletal		
Osteoporosis	TBI/radiation	Periodic bone densitometry
Avascular necrosis	Corticosteroids	
Second cancers	TBI/radiation	Periodic cancer screening
	Chemotherapy Chronic GVHD	

GVHD, Graft-versus-host disease; *TBI,* total body irradiation.

Organ-Specific Late Effects

A multitude of pre-, peri- and post-HCT factors determine a patient's overall risk for developing specific late complications. Risk factors include age at the time of HCT, sex, and lifestyle factors such as tobacco use. In addition, patients may have preexisting comorbidities such as chronic renal failure that can be exacerbated by chemotherapy, radiation, and other medications they receive to treat their malignancy and during HCT. Exposure to chemotherapy and radiation as part of the initial treatment of the underlying hematologic disorder or as part of the conditioning regimen given before HCT also can contribute to organ-specific complications. Allogeneic HCT recipients who develop GVHD require long-term, and at times lifelong, treatment with glucocorticoids, calcineurin inhibitors (e.g., cyclosporine or tacrolimus), or other immunosuppressive agents and can be prone to developing medication-related side effects, infections, and second malignancies, especially those associated with chronic immunodeficiency.

Although any organ system can be involved, certain organs have a greater predilection for late-onset problems post-HCT. Cataracts develop in more than one-third of patients by 5-years posttransplantation and often require surgical therapy.[229] Hypothyroidism can be seen in up to 50% and hypogonadism in up to 90% of HCT survivors.[230-232] The majority of HCT survivors become permanently sterile, although HCT without TBI can be fertility sparing in nearly one-third of men and women.[231,233] Prepubertal children may retain fertility, although secondary sexual development may be delayed. Up to 50% of children undergoing HCT also develop growth retardation.[234] Musculoskeletal complications, including osteoporosis and avascular necrosis, can be particularly debilitating. An increased incidence of cardiovascular events and diabetes has also been reported.[225,235] The risk for most organ-specific late complications continues to increase with time, and continued surveillance for these problems is indicated in all HCT survivors.

Second Cancers

Secondary cancers are a rare but devastating complication of HCT. They account for 5% to 10% of deaths among greater-than-2-year survivors. These malignancies can be broadly categorized as post-transplant lymphoproliferative disorders (PTLDs), hematologic malignancies, and solid cancers.[236-238]

PTLDs comprise a heterogeneous group of lymphoid proliferations, primarily involving B lymphocytes that develop as a result of uncontrolled Epstein-Barr virus (EBV) infection. They occur almost exclusively in allogeneic HCT recipients, with an overall incidence rate of 1% to 2%; they typically manifest soon after transplantation with more than 80% of cases diagnosed within the first year.[236,237,239] Because T cells play an important role in preventing proliferation of EBV-infected lymphocytes, removal of T cells from the hematopoietic graft source is a strong risk factor for PTLD.[240] A greater degree of immunosuppression, such as that resulting from GVHD and use of grafts from unrelated or HLA-mismatched donors, also increases the risk for PTLD. Treatment of PTLD is often challenging, and available treatments are not very effective. Withdrawal of immunosuppression is usually attempted first but can be difficult in patients with active GVHD. Treatment options include antiviral therapy with acyclovir or ganciclovir, multiagent chemotherapy, anti-CD20 monoclonal antibody rituximab, or infusion of EBV-specific cytotoxic lymphocytes. Because PTLD is associated with high mortality rates, active surveillance for EBV reactivation in high-risk settings and initiation of preemptive therapy, often with rituximab, is currently under investigation.

Secondary myelodysplastic syndrome (MDS) and acute myeloid leukemia (AML) can be seen in 5% to 15% of autologous HCT recipients but are extremely rare among allogeneic HCT recipients. They usually occur following a latency period of 2 to 5 years.[236,237,241] Bone-marrow evaluation can show cytogenetic abnormalities characteristic of other treatment-induced AML/MDS (e.g., balanced translocations to 11q23, monosomy of 5q and 7q or multiple, complex chromosomal aberrations). Risk factors for secondary MDS/AML include older age at transplant; the type, intensity, and duration of pre-HCT chemotherapy (especially alkylating agents); and use of TBI. Outcomes are very poor and long-term survival rates are less than 20%, sometimes following a second allograft for this new malignancy.

Secondary solid cancers have a latency period of 3 to 5 years following HCT. Subsequently, their incidence continues to rise with time and is higher than what may be expected in age- and sex-matched general populations. Their cumulative incidence ranges from 1% to 2% at 5 years, 2% to 6% at 10 years, and 4% to 15% at 15 years posttransplantation.[13,236,237] Younger age at

Table 110-6 Screening Guidelines for Common Cancers After Hematopoietic Cell Transplantation

Site	Screening Recommendations
Breast	Mammogram annually starting at age 40; in women who have received ≥20 Gy to the chest region begin at age 25 or 8 years after radiation, whichever is later
Cervix	Papanicolaou test every year (for regular Papanicolaou test) or every 2 years (for liquid-based Papanicolaou test); may screen every 2 to 3 years after age 30 if patient has three consecutive normal tests
Colorectal	Beginning at age 50, fecal occult blood annually and/or flexible sigmoidoscopy every 5 years, or double-contrast barium enema every 5 years, or colonoscopy every 10 years; certain high-risk groups (e.g., patients with inflammatory bowel disease) may need earlier initiation and more frequent screening
Lung	Yearly pulmonary examination with imaging as appropriate
Oral	Yearly oral cavity examination
Thyroid	Yearly thyroid examination
Skin	Yearly skin examination

transplantation, use of TBI, and chronic GVHD are important risk factors for solid cancers. Solid cancers at a variety of sites have been reported, including cancers of the head and neck, liver, brain and nervous system, thyroid, and bone and connective tissue. Because there is no plateau in the incidence of secondary solid cancers after HCT, their overall risk has not been completely realized, and longer follow-up than what is currently available is needed before the true magnitude of risk will become apparent. Lifelong cancer screening is recommended for all HCT survivors according to established guidelines (Table 110-6).[12]

Quality of Life After Transplantation

Despite the early morbidity associated with HCT, the majority of transplant survivors attain high levels of physical and psychologic quality of life (QOL) and return to full-time employment by 3 to 5 years posttransplant.[224,242-249] However, up to 20% to 40% of long-term survivors continue to have functional, psychologic, and cognitive impairments years after HCT.[227,250,251] The major risk factors for poor QOL are older age and advanced disease at transplantation, chronic GVHD, and presence of medical late effects.[243,244,246,252] Although chronic GVHD is a strong predictor of poor QOL, the overall health and functional status improves with resolution of GVHD and eventually reaches a level comparable to that seen in patients with no history of chronic GVHD.[252,253] Sex-specific differences in QOL have also been observed, with females more likely to report impairments in psychologic and sexual domains.[243,254] Cognitive deficits, particularly involving executive function, memory, and motor skills, have been reported in 30% to 60% of HCT survivors.[250,255-259] The risk for developing these neuropsychologic sequelae is increased in patients receiving transplantation at an older age, use of TBI-based conditioning regimens, and cyclosporine.

GRAFT-VERSUS-HOST DISEASE

GVHD is a clinicopathologic syndrome of T cell–mediated alloreactivity that commonly occurs as a complication of allogeneic HCT and leads to significant morbidity and mortality (also see Chapter 109). It is usually classified as acute GVHD or chronic GVHD.[260] Acute GVHD is further classified as classic acute GVHD (onset ≤100 days) and persistent, recurrent, or late-onset acute GVHD (onset >100 days). In the absence of clinical features characteristic of acute GVHD, chronic GVHD is called classic chronic GVHD. When features of both acute and chronic GVHD appear together, it is classified as overlap syndrome, based upon a consensus conference–proposed definition.

Current understanding of the pathogenesis of GVHD suggests that alloreactive donor T lymphocytes recognize histocompatibility antigens on host cells and initiate secondary inflammatory injury, leading to the clinical symptoms of GVHD.[261,262] This alloreactive response can be initiated or accelerated by conditioning regimen–induced tissue injury with release of proinflammatory cytokines, primarily IL-1 and TNF-α.[263-266] GVHD is more frequent and more severe in recipients of partially matched or histoincompatible transplants, suggesting that major histocompatibility complex–encoded molecules may be the prime antigenic targets initiating the alloreactive T-cell response.[120,122,267] Minor histocompatibility antigens also play an important role in its pathogenesis, especially in HLA-identical sibling donor grafts.[268] Activated donor-derived T cells produce IL-2 and interferon-γ, expand and differentiate into effector cells, and recruit mononuclear phagocytes and neutrophils, which ultimately yield host tissue destruction, primarily through apoptosis.[261,262,265,269-271] T cell–depletion of the graft reduces the risk for acute and chronic GVHD, albeit at the cost of increasing risks for disease relapse due to blunting of the graft-versus-tumor response.[272,273] Alternative mechanisms may also be involved in the pathogenesis of chronic GVHD, including autoreactivity, loss of self-tolerance, and B-cell dysregulation.[261,274,275]

Acute Graft-Versus-Host Disease

Risk Factors and Clinical Features

Up to 50% of patients receiving HLA-identical sibling-donor and up to 90% of patients receiving URD HCT develop acute GVHD.[120,122,267,276] Donor-recipient HLA disparity is the most important risk factor for acute GVHD.[120,277] Additional risk factors include increasing recipient and donor age,[267,276,278,279] use of alloimmunized donors such as parous women,[278,279] and HCT from unrelated instead of sibling donors.[120,278] Use of peripheral blood stem cells instead of bone marrow as graft source may be a particular risk for chronic GHVD.[280,281] Among recipients of UCB, acute GVHD occurs in 20% to 60% of patients; incidence of acute GVHD, though of only moderate severity, may be higher among recipients of double UCB transplantation.[282-285]

The skin, liver, and gastrointestinal tract are the most common sites of GVHD. Acute GVHD of the skin is characterized by a maculopapular rash that, when severe, can lead to bullae or even resemble toxic epidermal necrolysis. Hepatic involvement manifests as cholestatic hepatitis with marked elevation of serum bilirubin and alkaline phosphatase levels but usually only mild transaminase alterations. In the intestine, upper gastrointestinal tract GVHD can produce nausea, vomiting, and anorexia, whereas small bowel and colon GVHD produces large-volume secretory diarrhea. The diagnosis is clinical but frequently requires histologic confirmation to distinguish it from other frequent toxicities in the early posttransplantation period (e.g., hypersensitivity drug rash, drug-induced cholestasis, SOS, or infectious enteritis). The histologic hallmark of acute GVHD is apoptosis of the proliferative and regenerative cell layer of the epidermis, intestinal or biliary epithelium.

Acute GVHD is graded according to the organs involved (skin, liver, or gastrointestinal tract) and the extent (stage) of each organ involvement.[286,287] Mild to moderate (grade I or II) GVHD is characterized by limited organ involvement and carries an excellent prognosis. Severe (grade III or IV) GVHD has extensive multiorgan involvement with significant morbidity and poor survival, commonly progresses to chronic GVHD, and is associated with an increased risk for secondary opportunistic infections.[288,289]

Prophylaxis of Graft-Versus-Host Disease

The most effective techniques for GVHD prevention have involved ex vivo depletion of donor T lymphocytes, most often coupling immunologic recognition (monoclonal anti–T cell antibodies) with depletion techniques (immunomagnetic beads, complement cytotoxicity, or toxin immunoconjugates). Although vigorous T cell–depletion prevents acute GVHD, it also increases the risk for graft failure and neoplastic relapse after transplantation.[272]

Pharmacologic immunosuppression administered in the first several months after transplantation can prevent or blunt the initiating T-cell recognition and proliferative response that triggers GVHD and can allow development of immune system tolerance and complete lymphohematopoietic chimerism. Methotrexate, corticosteroids, ATG, cyclosporine, tacrolimus, MMF, and sirolimus have been used for prophylaxis of GVHD and have successfully reduced both the frequency and the severity of clinical GVHD.[276,288,290-298] Despite the potential role of inflammatory cytokines in initiation and amplification of GVHD, clinical blockade of IL-1, IL-2, or TNF-α has not been effective in GVHD prophylaxis.[299-301]

Treatment of Acute Graft-Versus-Host Disease

Therapy for acute GVHD requires both immunosuppression to blunt the T cell–induced tissue injury and appropriate supportive care. Corticosteroids are the mainstay of initial therapy for acute GVHD.[288,298,302,303] GVHD involving limited areas of the skin can be treated with topical corticosteroids alone. Oral beclomethasone can be used to treat early-stage GVHD of the upper gastrointestinal tract.[304] Corticosteroids (1 to 2 mg/kg/day prednisone) are initial therapy for more advanced GVHD and have response rates of 30% to 50%.[305-307] Alternative treatment regimens include cyclosporine or ATG alone or in combination with corticosteroids; however, no regimen has shown a consistent increase in response rates or improvement in survival compared to corticosteroids alone.[305,308,309] In a recent large randomized phase II trial comparing corticosteroids with MMF, pentostatin, etanercept, or denileukin diftitox, efficacy and toxicity data suggested the combination of MMF and corticosteroids to be most promising.[310] This combination is presently being tested in a phase III trial compared to corticosteroids alone for treatment of acute GVHD. Other investigational therapies include sirolimus, alemtuzumab, and infusion of mesenchymal stem cells. Prognosis is serious for patients with steroid-resistant disease, which is GVHD that does not respond to initial therapy with corticosteroids. Up to 10% to 40% of patients will respond to salvage therapy with ATG or other drugs such as sirolimus, tacrolimus, MMF, pentostatin, or cyclosporine, either as single agents or in combination.[311-314] Monoclonal antibodies and immunotoxins directed against T cells or inflammatory cytokines have been investigated, although their effectiveness has not been demonstrated outside of small case series. Specific agents with reported activity in steroid-refractory acute GVHD include pentostatin,[315] etanercept and infliximab (TNF-α receptor blockers),[316-318] daclizumab and denileukin diftitox (IL-2 receptor inhibitors),[319-321] and visilizumab (anti-CD3 antibody).[322] Extracorporeal photochemotherapy has also been reported to have some efficacy in cutaneous and hepatic steroid-refractory acute GVHD.[323] In addition to effective immunosuppression, successful management of acute GVHD involves attention to supportive care, particularly skin care, nutrition, and limitation of polypharmacy-associated drug interactions. Infections are a leading cause of death in patients with GVHD, and attention should be paid to infection surveillance and prophylaxis.

Chronic Graft-Versus-Host Disease

Risk Factors and Clinical Features

Chronic GVHD is a complex syndrome in recipients of allogeneic HCT that occurs later, typically between 3 to 7 months posttransplant, although it can also begin before 3 months and even beyond 2 years. Its incidence ranges from 30% to 50% in HLA-matched sibling donor transplants to 50% to 70% in HLA-matched URD transplants, and it is the leading cause of nonrelapse late mortality in allogeneic HCT survivors.[223,324-328] Recipients of UCB grafts have risks that are lower compared to matched adult URD HCT and comparable or even lower compared to matched related-donor HCT recipients.[99,282,283] Chronic GVHD occurs most frequently in patients with preceding acute GVHD but can also manifest de novo without any preceding acute GVHD. The distinction between classic chronic GVHD and overlap syndrome requires attention to clinical symptoms and signs.

Acute GVHD is the most important risk factor for development of subsequent chronic GVHD.[327,329] Use of mismatched or unrelated donors and transplantation using peripheral blood–derived hematopoietic stem cells instead of bone marrow also increases its risk.[280,328,330,331] Other reported risk factors for chronic GVHD include older recipient age, use of a female donor, CMV seropositivity, high graft $CD34^+$ cell count, treatment with donor lymphocyte infusion, and underlying diagnosis of chronic myeloid leukemia or aplastic anemia.[325-329] Similar to acute GVHD, in vitro or in vivo T cell–depletion of the graft can reduce the incidence of chronic GVHD.[292,332-334]

Chronic GVHD can affect any organ system; however, certain pathognomonic clinical signs and symptoms have to be present for establishing its diagnosis (Table 110-7).[260] Other clinical manifestations, though not diagnostic of chronic GVHD, can be characteristic, but they may resemble acute GVHD as well. Additional investigations, including biopsies, might be needed to verify the diagnosis and to rule out other causes, such as infections, drug effects, and malignancies.[335] The skin, mouth, eyes, and liver are the most commonly involved sites of chronic GHVD. The cutaneous manifestations resemble autoimmune disease and can include poikiloderma, lichen planus–like eruptions, or scleroderma (sclerosis). An inflammatory dermatitis can progress to severe dermal and periarticular fibrosis with loss of skin appendages (hair and sweat glands) as well as significant skin tightness, fasciitis, and loss of joint flexibility. Additional manifestations include dry eyes and dry mouth, which can resemble Sjögren syndrome clinically and histologically; enteritis with anorexia,

Table 110-7 Common Clinical Manifestations of Chronic Graft-Versus-Host Disease

Organ System	Clinical Manifestations
Cutaneous	Poikiloderma, lichen planus, dermal sclerosis, morphea-like features, hypopigmentation or hyperpigmentation, ichthyosis, nail dystrophy, onycholysis
Ocular	Keratoconjunctivitis sicca, conjunctivitis, corneal ulcerations
Oral	Lichen planus, hyperkeratotic plaques, xerostomia, mucosal atrophy, ulcers, restriction of mouth opening from sclerosis
Pulmonary	Bronchiolitis obliterans, bronchiolitis obliterans–organizing pneumonia
Gastrointestinal	Esophageal web and strictures, malabsorption syndrome, exocrine pancreatic insufficiency
Hepatic	Cholestasis
Genitourinary	Vaginal stenosis or scarring, lichen planus
Musculoskeletal	Fasciitis, joint contractures from sclerosis, myositis or polymyositis, arthritis
Hematopoietic	Thrombocytopenia, eosinophilia, lymphopenia, hemolytic anemia, hypogammaglobulinemia

early satiety, malabsorption, weight loss and failure to thrive, or esophageal dysmotility or stricture; and cholestatic (or sometimes hepatitic) jaundice. Pulmonary involvement in the form of bronchiolitis obliterans is an uncommon manifestation but can be particularly debilitating and dangerous. In addition, the profound immune dysfunction associated with chronic GVHD due to hypogammaglobulinemia, impaired cellular immunity, and functional asplenia, greatly increases the risk for secondary infections from bacteria, viruses, and fungi. After the onset of chronic GVHD, 25% to 40% of patients die within 2 years, often of secondary infections.[324,325,327]

Chronic GVHD can be classified as mild, moderate, or severe depending on the number of organs involved and the degree of individual organ involvement.[260] In general, factors associated with an adverse prognosis include thrombocytopenia, progressive onset from acute GVHD, poor performance status, lack of response to initial therapy, and extensive skin or lung involvement.[324,325,336]

Treatment of Chronic Graft-Versus-Host Disease

Although acute GVHD is one of the strongest predictors for chronic GVHD, strategies to limit acute GVHD, such as prolonging or intensifying initial immunosuppression, have not been consistently effective in preventing subsequent chronic GVHD.[337,338] As with acute GVHD, the specific immunosuppressive therapy for chronic GVHD is most often corticosteroids, usually in combination with cyclosporine.[339,340] The ongoing and long-lasting nature of the syndrome demands that reduced doses and, if possible, alternate-day steroid therapy be used to minimize chronic complications of prolonged corticosteroid therapy. Typical corticosteroid regimens start with daily prednisone 1 mg/kg/day, and responding patients are tapered down to 0.5 to 1 mg/kg every other day and continued on this dose for 6 to 9 months beyond any active GVHD symptoms, followed by a slow withdrawal of immunosuppression. Longer therapy may be required for some patients, and early withdrawal of therapy has been frequently accompanied by flares of chronic GVHD. Salvage therapies, including high-dose corticosteroids, sirolimus, tacrolimus, MMF, thalidomide, azathioprine, and hydroxychloroquine, have been tried with limited response rates.[326] Newer approaches currently being investigated as potential therapies for chronic GVHD include modulation of T-cell function, B-cell depletion, induction of immune tolerance, and cytokine blockade.[337] Small uncontrolled studies have reported the use of pentostatin, alemtuzumab, and ATG to inhibit T-cell function and rituximab to eliminate B cells with response rates of 30% to 50%.[298,332,334,341,342] T-cell immunomodulation using extracorporeal photopheresis has been shown to have some activity, especially in sclerotic cutaneous chronic GVHD.[343,344] Preliminary studies using daclizumab, etanercept, and infliximab for blockade of the cytokine-mediated inflammatory response have also shown short-term responses.[316,345] The treatment of chronic GVHD demands particular attention to prophylaxis and aggressive therapy of secondary opportunistic infections. Most successful strategies for treating chronic GVHD incorporate long-term reduced-dose immunosuppressive therapy, aggressive antimicrobial prophylaxis, and supportive care. Strategies are being studied that favor development of donor-derived regulatory T cells (Tregs), which may facilitate the development of immunologic tolerance, including avoidance of calcineurin inhibitors (cyclosporine or tacrolimus) or photopheresis.

FUTURE DIRECTIONS

Complications of HCT are one of the major barriers to the wider application of transplantation for a variety of diseases. The impact of newer transplantation modalities, including the use of nonmyeloablative or reduced-intensity conditioning regimens, alternative donor transplantation with UCB, and incorporation of immune-based therapies within transplantation regimens, on early and late complications are areas of vigorous current investigation. Better tools to predict the risk for post-HCT complications and nonrelapse mortality are needed as well.[346,347] Genomic and proteomic approaches to HCT complications are being investigated to monitor and predict complications.[348,349] Although they are some years from use in clinical practice, these approaches could have many potential applications in transplantation, including prediction of risk for complications and GVHD, refining donor selection, and use of pharmacogenomic data to individualize conditioning regimens and immunosuppression, all to improve the safety and effectiveness of HCT.

CHAPTER 111

HUMAN BLOOD GROUP ANTIGENS AND ANTIBODIES

Connie M. Westhoff, Jill R. Storry, and Beth H. Shaz

Pretransfusion testing includes ABO and Rh type and antibody screening to determine whether a patient has an unexpected red blood cell (RBC) antibody. If the antibody screen is positive, an identification panel is performed to identify the specificity of the antibody. Unexpected antibodies can be clinically significant causing hemolysis (e.g., acute or delayed hemolytic reaction) after transfusion of RBCs carrying the reciprocal antigen, or can be insignificant. The clinical significance of an antibody is assessed by correlating the serologic information with clinical experiences reported in the literature and with the patient's medical history. Notably, the majority of clinically significant antibodies (outside the ABO system) are in response to RBC antigen exposure either through transfusion or pregnancy. Other antibody characteristics that are used to predict clinical significance include immunoglobulin class and in vitro characteristics such as strength of reactivity and titer; however, no foolproof method exists to predict the clinical significance. For antibodies with well-known clinical significance, antigen-negative blood is selected for transfusion. Predicting clinical significance is more difficult when a patient has an antibody to a novel or rare high-prevalence antigen and requires a transfusion but antigen-negative blood is not available.

ERYTHROCYTE BLOOD GROUP ANTIGENS

Erythrocyte blood group antigens are polymorphic, inherited, carbohydrate or protein structures located on the surface of the RBC membrane. There are more than 300 blood group antigens, most of which are included in 30 different blood group systems (Table 111-1). The protein antigens are primarily located on integral transmembrane proteins, but a few are on glycosylphosphatidylinositol (GPI)–linked proteins (Fig. 111-1). Some antigens are carbohydrates attached to proteins or lipids, some require a combination of a specific portion of protein and carbohydrate, and a few antigens are carried on proteins that are adsorbed from the plasma. Many of the proteins carrying blood group antigens reside in the erythrocyte membrane as complexes with other proteins.

Recognition of a new blood group antigen begins with discovery of an antibody. When an individual whose RBCs lack an antigen is exposed to RBCs that possess the antigen, he or she may mount an immune response and produce antibodies that react with the antigen. Depending on the characteristics of the antibody and the number and topology of antigens in the RBC membrane, the interaction in vivo between antibody and antigen may result in removal of antibody-coated red cells by the reticuloendothelial system or in hemolysis if complement is activated.

In blood group testing, most assays are designed to detect antibody-antigen binding with clumping of the RBCs as the detectable endpoint. The ability to detect and identify blood group antigens and antibodies has contributed significantly to current safe supportive blood transfusion practice, to the appropriate management of pregnancies at-risk for hemolytic disease of the fetus and newborn (HDFN), and to management of hematopoietic progenitor cell and solid organ transplantation.

Terminology

Some blood group systems bear the family surname in which the antibody was first discovered (Kell, Kidd, Duffy, etc.), with abbreviations to indicate antigens (K/k, Jk^a/Jk^b, and Fy^a/Fy^b etc.). Others have been given letter designations (A, B, D, M, N, etc.). A committee for terminology of RBC surface antigens and alleles, organized by the International Society of Blood Transfusion (ISBT), works to standardize terminology of new blood group antigens and the coding alleles.

DNA-Based Typing for Blood Group Antigens

The majority of genes encoding blood group antigens have been identified and cloned,[1] and the molecular basis of most blood group antigens has been determined.[2,3] Details concerning the alleles associated with blood group antigens are found on the ISBT nomenclature and the Blood Group Antigen Gene Mutation Database (BGMUT) websites (www.ncbi.nlm.nih.gov/gv/mhc/xslcgi.cgi?cmd=bgmut/home; www.isbtweb.org/working-parties/red-cell-immunogenetics-and-blood-group-terminology/). Knowledge of the genes has advanced understanding of the structure and function of the components carrying antigens and resulted in an appreciation of diseases associated with loss of expression of some blood groups—for example, null phenotypes (Table 111-1). Of importance, knowledge of the gene has made it possible to perform DNA analyses to predict the serologic phenotype, to determine gene dosage (zygosity), to perform noninvasive fetal typing, and to type for numerous blood group antigens in a single assay.

Although the simple hemagglutination test remains the principal assay for RBC antigen typing for ABO and Rh, antibody screen, and compatibility testing; genotyping for minor blood group antigens has become commonplace in several clinical situations (Table 111-2). These include determination of the extended blood group phenotype in patients who are multiply transfused, which avoids false typing due to contaminating donor RBCs and aids determination of antibody specificity. This approach is also preferred in patients with strongly DAT-positive RBCs, as well as for typing for antigens when no serologic reagents are available and for fetal typing from amniocytes or from free DNA present in the maternal plasma. In these instances and others (Table 111-2), hemagglutination is not helpful and genomic analysis is a useful adjunct to routine testing. High-throughput genotyping systems have enabled blood centers to screen donors for a large number of antigens in a single assay.

Blood Group Antibodies

The common causes of immunization against blood group antigens are transfusion, pregnancy, transplantation, or occasionally, practices such as sharing needles. "Naturally occurring" antibodies are not a result of RBC exposure; rather, microbes encountered by way of the

Table 111-1 Blood Group Systems, Antigens, Expression, and Disease Associations

ISBT System Name (Number)	Gene Name (ISBT)	Predicted Topology (Number of Amino Acids AA)	Component Name	Principal Associated Blood Group Antigens (null phenotype)	Present in Other Tissue	Disease Association	Function
ABO (001)	*ABO*	Glycosyl-transferases Type II (354 AA)	Carbohydrate	A, B, AB, A1 (group O)	Secretions, platelets, broad tissue distribution	Altered in some hematologic disorders, leukemia	Glycosylation
MNS (002)	*GYPA (MN)* *GYPB (Ss)*	Type I (131 AA) Type I (72 AA)	GPA GPB	M, N, S, s, U, Vw; M^k M^k lack GPA and GPB; En(a–) lack GPA; S–s–U– lack GPB	Renal endothelium and epithelium	Decreased *P. falciparum* invasion May be receptor for *E. coli*	Negative charge on sialic acid; receptor for microbes
P (003)	*A4GALT*	Galactosyl-transferase Type II (353 AA)	Carbohydrate	P1, Pk (P1–, PP1Pk–)	Lymphocytes, granulocytes, monocytes, platelets	Receptor *E. coli* and *Parvovirus-B19* Miscarriage	Glycosylation
Rh (004)	*RHD* *RHCE*	Multipass—12 spans (417 AA)	RhD RhCE	D, C, E, c, e, G, V/VS (Rh_{null} syndrome)	RBC-specific	Hemolytic anemia; stomatocytosis Reduced expression and mosaicism in hematologic malignancies	Structural link to underlying cytoskeleton
Lutheran (005)	*LU*	Type I IgSF (597 AA) (557 AA)	Lutheran glycoprotein B-CAM	Lu^a, Lu^b, Lu3, Au^a, Au^b (recessive Lu(a–b–))	Broad tissue distribution Not on lymphocytes, granulocytes, monocytes or platelets	Increased expression possibly involved in vasoocclusion in sickle cell disease	Possibly adhesion; may mediate intracellular signaling Binds to laminin
Kell (006)	*KEL*	Type II (732 AA)	Kell glycoprotein	K, k, Kp^a, Kp^b, Ku, Js^a, Js^b (K_0 or K_{null})	Broad tissue distribution Bone marrow, fetal liver, testes, brain, heart, skeletal muscle	Depressed in McLeod syndrome (see XK)	Cleaves big endothelin 3 to ET-3 (a potent vasoconstrictor)
Lewis (007)	*FUT3 (LE)*	Not endogenous to RBCs Type II (361 AA)	Carbohydrate Adsorbed from plasma	Le^a, Le^b, Le^{ab}, Le^{bh}, ALe^b, BLe^b (Le(a–b–))	Saliva and body fluids Blood cells, GI, skeletal muscle, kidney, adrenal	Increased expression in fucosisdosis	Fucosyl transferase
Duffy (008)	*DARC (FY)*	Multipass—7 spans (338 AA)	Fy glycoprotein	Fy^a, Fy^b, Fy3, Fy6 (Fy(a–b–))	Broad tissue distribution Endothelial and epithelial cells, Purkinje cells, colon, lung, spleen, thyroid, thymus, kidney	*Plasmodium vivax* receptor RBC null-resistant to *P. vivax*	Chemokine receptor
Kidd (009)	*SLC14A1 (JK)*	Multipass—10 spans (389 AA)	Kidd glycoprotein	Jk^a, Jk^b, Jk3 (Jk(a–b–) or Jk_{null})	Kidney: vasa recta endothelium Renal medulla	Urine concentrating defect	Urea transport
Diego (010)	*SLC4A1 (DI)*	Multipass—14 spans (911 AA)	Band 3, AE1 (anion exchanger 1)	Di^a, Di^b, Wr^a, Wr^b, (1 reported—transfusion dependent; predicted to be incompatible with life)	Kidney: intercalated cells of distal and collecting tubules	Southeast Asian ovalocytosis, hereditary spherocytosis, renal tubular acidosis	Anion transport CO_2/HCO_3^- exchange
Yt (011)	*ACHE (YT)*	GPI-linked (557 AA)	Acetyl-cholinesterase	Yt^a, Yt^b	Brain, muscle, nerves	Absent from PNH III RBCs	Enzymatic

Continued

Table 111-1 Blood Group Systems, Antigens, Expression, and Disease Associations—cont'd

ISBT System Name (Number)	Gene Name (ISBT)	Predicted Topology (Number of Amino Acids AA)	Component Name	Principal Associated Blood Group Antigens (null phenotype)	Present in Other Tissue	Disease Association	Function
Xg (012)	*MIC2 (XG1)*	Type I (180 AA) (163 AA)	Xg^a glycoprotein	Xg^a	The antigen may be restricted to RBC, but CD99 has broad tissue distribution		Adhesion molecule
Scianna (013)	*ERMAP (SC)*	Type I (475 AA)	ERMAP	Sc1, Sc2, Sc3, Rd (Sc –1, –2, –3)			Possible adhesion
Dombrock (014)	*ART4 (DO)*	GPI-linked (314 AA)	Do glycoprotein; ART 4	Do^a, Do^b, Gy^a, Hy, Jo^a (Gy(a–))	Lymphocytes, spleen, lymph notes, GI, ovary, testes, heart, liver	Absent from PNH III RBCs	Enzymatic
Colton (015)	*AQP1 (CO)*	Multipass—6 spans (269 AA)	Aquaporin	Co^a, Co^b, Co3 (Co(a–b–))	Broad tissue distribution Kidney, liver, gallbladder, eye, capillary endothelium	Monosomy 7, congenital dyserythropoietic anemia	Water transport
Landsteiner-Wiener (016)	*ICAM4 (LW)*	Type I IgSF (241 AA)	LW glycoprotein ICAM-4	LW^a, LW^b, LW^{ab} (LW(a–b–))		Depressed in some malignant diseases; decreased in Rh_{null} syndrome	Ligand for integrins
Chido/ Rodgers (017)	*C4A, C4B (CH/RG)*	Not endogenous to RBC (1191 AA)	C4A; C4B	Ch1, Ch2, Rg1	Adsorbed from plasma	Certain phenotypes increased susceptibility to autoimmune conditions and infections C4-deficient predisposes for SLE	Part of the complement cascade
H (018)	*FUT1(H)*	Fucosyl-transferase Type II (365 AA)	Carbohydrate	H (Bombay O_h)	Broad distribution Soluble—all fluids except CSF in secretors	Decreased in some tumor cells Increased in hematopoietic stress	Glycosylation
Kx (019)	*XK (XK)*	Multipass—10 spans (444 AA)	XK glycoprotein	Kx (McLeod)	Fetal liver, adult skeletal muscle, brain, pancreas, heart	X-linked midlife onset neuropathy, elevated CPK, muscular dystrophy, acanthocytosis; sometimes associated with CGD	Transport; possible neuro-transmitter
Gerbich (020)	*GYPC (GE)*	Type I (128 AA) (107 AA)	GPC GPD	Ge2, Ge3, Ge4 (Leach phenotype)	Fetal liver, renal endothelium	Hereditary elliptocytosis, hemolytic anemia, receptor *P. falciparum*	Structural Interacts with protein 4.1 and p55
Cromer (021)	*CD55 (CROM)*	GPI-linked (347 AA)	DAF	Cr^a, Tc^a, Tc^b, Tc^c, Dr^a, Es^a, IFC (Inab)	Vascular endothelium Epithelial GI, GU, CNS Soluble form in plasma and urine	Absent from PNH III RBCs Dr^a is receptor for uropathogenic *E. coli*	Complement regulation; binds C3b; disassembles C3/C5 convertase

Table 111-1 Blood Group Systems, Antigens, Expression, and Disease Associations—cont'd

ISBT System Name (Number)	Gene Name (ISBT)	Predicted Topology (Number of Amino Acids AA)	Component Name	Principal Associated Blood Group Antigens (null phenotype)	Present in Other Tissue	Disease Association	Function
Knops (022)	*CR1 (KN)*	Type I (1998 AA)	CR1	Kn^a, Kn^b, McC^a, Sl^a, Yk^a, KCAM (no nulls reported)	Blood cells, glomerular podocytes, follicular dendritic cells	Antigens depressed in certain autoimmune and malignant conditions	Complement regulation; binds C3b and C4b; mediates phagocytosis
Indian (023)	*CD44 (IN)*	Type I (341 AA)	Hermes antigen	In^a, In^b	Wide tissue distribution	1 case—congenital dyserythropoietic anemia	Binds hyaluronic acid; mediates adhesion of leukocytes
Ok (024)	*BSG (OK)*	Type I IgSF (248 AA)	Basigin	Ok^a	All cells tested	Receptor *Plasmodium falciparum*	Possible adhesion
RAPH (025)	*MER2*	Multipass—4 spans (253 AA)	CD151	MER2 (Raph–)	Fibroblasts	Absence associated with renal disease and kidney failure

I (027)	*GCNT2*	*N*-acetyl-glucosaminyl-transferase type II (400 AA)	Carbohydrate	I (I– or i adult)	Broad tissue distribution	Cataracts in Asians	Glycosylation
Globoside (028)	*B3GALT3 or βGalNAcT1*	*N*-acetyl-galactosaminyl-transferase type II (331 AA)	Carbohydrate (Gb_4, globoside)	P (P–) P^k and p	Broad tissue distribution Placenta (trophoblasts and interstitial cells)	Receptor *E. coli* and *Parvovirus-B19* Spontaneous abortion	Glycosylation
GIL (029)	*AQP3 (GIL)*	Multipass—6 spans (292 AA)	AQP3	GIL (GIL–)	Board tissue distribution Kidney, prostate, GI tract, spleen, skin, eye		Glycerol/ water/ urea transport
RHAG (030)	*RHAG*	Multipass—12 spans (409 AA)	Rh-associated glycoprotein	RHAG1 or Duclos, RHAG2 or Ol^a, RHAG3 or DL, RHAG4 (Rh_{null} regulator)	RBC-specific but homologs RhBG, RhCG in kidney, liver, skin, GI tract	Hereditary overhydrated stomatocytosis	Ammonia transport

IgSF, Immunoglobulin super family; *ISGN,* International Society for Gene Nomenclature; *type I,* protein with a single pass through the RBC lipid bilayer with its amino terminus to the outside of the cell; *type II,* protein with a single pass through the RBC lipid bilayer with its amino terminus to the inside of the cell.

Table 111-2 Uses of DNA-Based Genotyping Assays for Transfusion Medicine

Type patients who have been recently transfused
Type RBCs coated with immunoglobulin
Type patients with AIHA (to select antigen-negative RBCs for transfusion and absorption of autoantibodies when searching for under-lying alloantibodies)
Type RBCs when commercial antisera are not available
Type for numerous blood group antigens in a single assay
Identify weak D and partial D (to determine candidate for Rh immune globulin or avoid use of limited Rh-negative donor supply)
Resolve blood group typing discrepancies
Determine paternal zygosity for *RHD* and HPA
Type fetus to determine risk for HDFN or NAIT

digestive tract and other mucosal surfaces regularly (e.g., anti-A, -B,) or sometimes (e.g., anti-M, -P, -P^k, -P1, -Le^a, -Le^b, -I, -IH) result in production of antibodies with these specificities. These are the most common antibodies present in children and nontransfused male patients and are primarily IgM. These multivalent IgM antibodies directed to carbohydrate antigens optimally bind and directly agglutinate to RBCs at temperatures below 37° C. Most are not clinically significant (outside of ABO). Exceptions occur if the antibody is reactive at 37° C and/or has an IgG component. Antibodies that are considered not to be clinically significant unless the antibody reacts in tests performed at 37° C include those to A1, P1, M, N, Lu^a, Le^a, Le^b, I, IH, and Sd^a antigens.

In contrast, antibodies occurring following immunization to protein antigens such as those in the Rh, Kell, Kidd, and Duffy blood group systems are primarily of the IgG isotype that react at 37° C and are detected by the indirect antiglobulin test (IAT). These bivalent antibodies optimally bind to, but do not directly agglutinate, RBCs at 37° C. The addition of an antiglobulin reagent (i.e.,

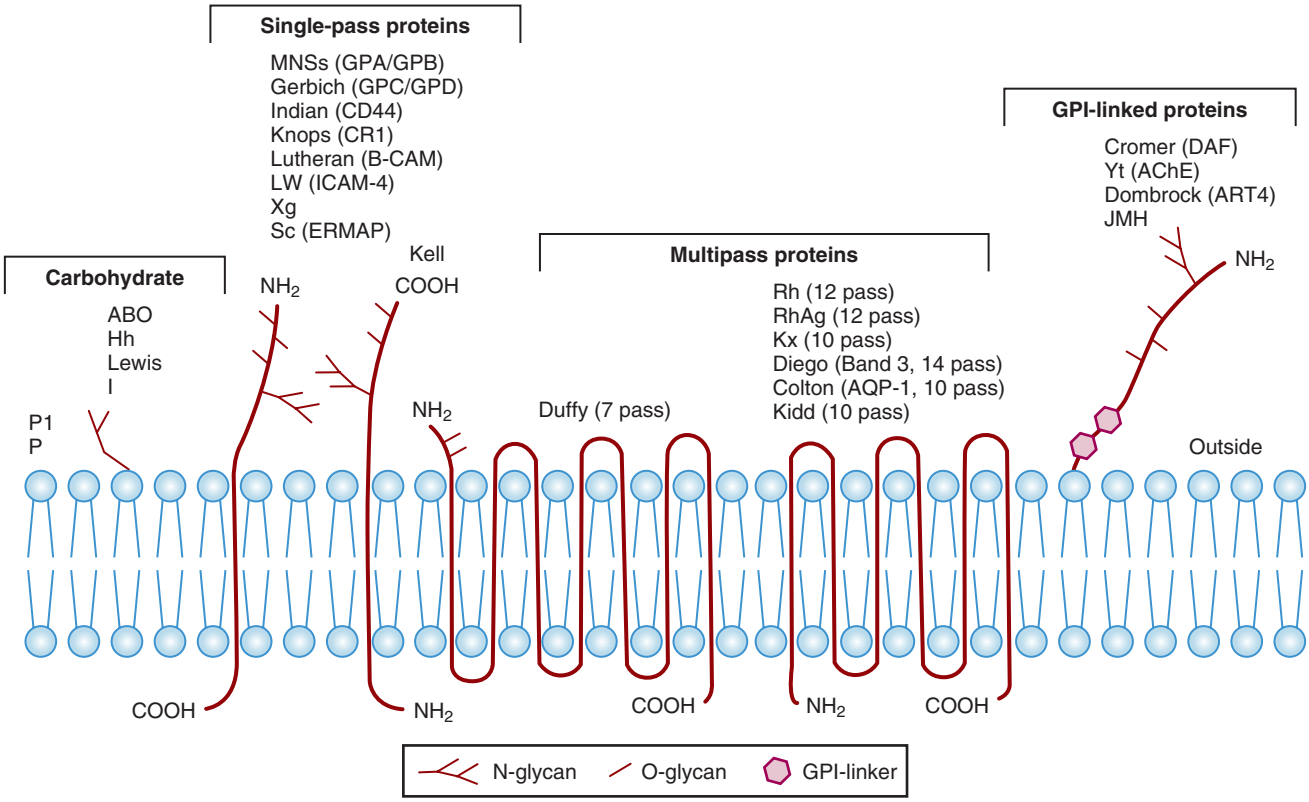

Figure 111-1 MODEL OF BLOOD GROUP PROTEINS IN THE RED BLOOD CELL (RBC) MEMBRANE. Schematic representation of the RBC molecules that carry blood group antigens and the predicted structure. These include carbohydrates, single and multipass proteins, and GPI-linked proteins in the RBC membrane.

antihuman IgG, also known as Coombs serum) is required to induce RBC agglutination. Most of these are clinically significant antibodies, with the exception of antibodies to Knops (KN), Chido/Rodgers (CH/RG) and JMH systems (Table 111-3 summarizes the immunoglobulin class and clinical significance associated with alloantibodies; see also box on Indirect Antiglobulin Test and Direct Antiglobulin Test).

Antibodies recognizing antigens in the ABO system are by far the most clinically significant and are present in nearly all individuals who lack the antigen (they typically appear by 4 months of age). Other clinically significant antibodies occur in the following approximate order, from the most to the least commonly encountered in transfusion practice: anti-D, anti-K, anti-E, anti-c, anti-Fy^a, anti-C, anti-Jk^a, anti-S, and anti-Jk^b. Clinically significant antibodies occur in 2% to 3% of immunized patients[4] but have a higher incidence of 35% to 55% in patients undergoing chronic transfusion.[5-8] The frequency of antibody production depends on the antigen immunogenicity and prevalence of the antigen in a population.

Compatibility Procedures and Location of Antigen-Negative Blood

Manual tube or gel-column methods based on agglutination of RBCs are the most common serologic assays performed in transfusion medicine laboratories.

ABO

Commercially available mouse monoclonal anti-A and anti-B are used to determine ABO type, and these reagents directly agglutinate RBCs at room temperature. To confirm the RBC ABO reactivity, the

Indirect Antiglobulin Test and Direct Antiglobulin Test

The indirect antiglobulin test (IAT) is used to detect alloantibodies in patient sera, or RBCs coated with antibody in vitro following incubation at 37° C, for example, antibody screening and identification, antigen typing, and crossmatching with donor RBCs. After incubation, unbound antibodies are removed from the RBCs by washing with saline, and an antiglobulin reagent containing either antihuman IgG or a mixture of antihuman IgG and monoclonal antihuman complement is added. Agglutination of all cells suggests the presence of an antibody to a high-prevalence antigen or the presence of an autoantibody; differential reactivity suggests the presence of antibodies to one or more specific RBC antigens.

The direct antiglobulin test (DAT) is used to detect the presence of antibody or complement (or both) on the surface of RBCs in vivo such as autoantibodies coating the patient's cells in warm autoimmune hemolytic anemia, cold hemagglutinin disease, or alloantibodies coating the patient's cells in immediate or delayed transfusion reactions or hemolytic disease of the fetus and newborn. Patient RBCs obtained in ethylenediaminetetraacetic acid (EDTA) are washed with saline and then incubated with a commercial antiglobulin reagent containing antihuman IgG or antihuman complement or a mixture of the two. Antiglobulin reagents containing anti-IgM or anti-IgA are available in specialized centers to detect coating of RBCs in vivo by antibodies of these isotypes.

Table 111-3 Characteristics of Some Blood Group Alloantibodies (Listed in Approximate Order of Clinical Significance)

			Clinical	
Antibody Specificity	**IgM**	**IgG**	**Transfusion Reaction**	**HDFN**
ABO	Most	Some	Immediate; mild to severe	Common; mild to moderate
H in Bombay	Most	Some	Immediate; mild to severe	Rare; Mild
Rh	Some	Most	Immediate/delayed; mild to severe	Common; mild to severe
RhAG	Rare	Most	Immediate/delayed; mild to severe	Mild to severe
Kell	Some	Most	Immediate/delayed; mild to severe	Mild to severe
Kidd	Few	Most	Immediate/delayed; mild to severe	Rare; mild
Duffy	Rare	Most	Immediate/delayed; mild to severe	Rare; mild
S	Some	Most	Delayed/mild	Rare; mild to severe

Xg^a	Rare	Most	None	None

HDFN, Hemolytic disease of the fetus and newborn.
*Most examples of these antibodies are both IgM and IgG.
†Seldom hemolysis of fetal cells but high incidence of recurrent spontaneous abortions.

plasma is tested for the presence of the corresponding agglutinins by testing with commercially available group A1 and group B RBCs. In both tests, agglutination is macroscopically visible.

Rh

Patient and donor RBCs are routinely tested for the presence of the D antigen in the Rh system. Reagents containing monoclonal anti-D that directly agglutinate D-positive RBCs (Rh-positive) suspended in saline at room temperature are commonly used for testing. Testing for expression of a weak D antigen on RBCs is required for donor centers, but is usually not performed on patient samples. Exceptions include typing the RBCs of a newborn when the mother is D-negative to determine whether she is a candidate for Rh immune globulin (RhIG) (see box on Rh Immune Globulin).

Antibody Screening

Patient plasma is incubated at 37° C with commercially available reagent RBCs of known antigen type. After incubation, unbound antibodies are removed by washing with saline, and an antiglobulin reagent containing either antihum an IgG (AHG), or a mixture of antihuman IgG and antihuman complement, is added. If the test is positive, the specificity of the antibody is determined by testing the plasma against a panel of different reagent RBCs (usually 10) varying in antigen phenotype (e.g. antibody identification).

Compatibility Testing

Once a patient is actively immunized to an RBC antigen and produces a clinically significant alloantibody, the patient is considered

Rh Immune Globulin

RhIG is a human plasma–derived hyperimmunoglobulin product consisting of IgG antibodies to D antigen that is administered to D-negative pregnant women who are at risk for D sensitization. RhIG is administered (a) at 28 weeks gestational age, (b) when there is a risk for fetal maternal hemorrhage through amniocentesis, trauma, or other procedures, and (c) postpartum in the case of a known or potential D-positive newborn or fetus. RhIG is sometimes administered outside of pregnancy to D-negative patients who receive D-positive blood products, most commonly platelet products. This is primarily considered for females of childbearing potential when the formation of anti-D has serious consequences. (Because the risk for D alloimmunization from platelet transfusion is less than 4%, the majority of D-incompatible platelets are given without RhIG administration.) RhIG in significantly higher doses is used to treat immune thrombocytopenic purpura (ITP) in patients who are D-positive and have not been spleenectomized.

For prevention of D-sensitization in the United States, 300 mcg are routinely administered, but dosing is increased if there is evidence of large fetal-maternal hemorrhage (300 mcg for every 15 mL of RBC exposure). The dose is calculated based on the estimated volume of D-positive RBCs from Kleihauer-Betke or flow cytometry testing. RhIG should be given within 72 hours, which was the time period for the original studies, but should not be withheld if not administered within this time period. Adverse events to low doses used to prevent D immunization include fever, chills, and pain at the injection site. Rarely, hypersensitivity reactions are noted. RhIG doses used to treat ITP are substantial: 50 mcg/kg for hemoglobin values ≥10 g/dL and 25 to 40 mcg/kg when hemoglobin is 8 to 10 g/dL. Adverse events include possible anemia, hemolysis, disseminated intravascular coagulopathy, and rarely, death.

immunized for life and should be transfused with antigen-negative RBCs, even if the antibody is no longer detectable. Patients with passively acquired antibody (e.g., neonates with maternal antibody; recipients of plasma and platelet products or Rh immune globulin) need to be transfused with antigen-negative RBCs only while the passive antibody is present. Selection of blood for transfusion to patients with alloantibodies requires typing of donor units for the corresponding antigen to identify antigen-negative units and crossmatch of the selected units with the patient's plasma. Antigen-negative units are provided by, or can be located by, most donor centers. Provision of antigen-negative blood will to some extent depend on the prevalence of the target antigen(s) in the donor population. Transfusion service staff is vital for communication between the patient's physician and/or consultant transfusion medicine specialist in order to determine the immediate and ongoing transfusion needs of the patient and to ensure that antigen-negative blood is available as appropriate. Understanding the risks and benefits of transfusion is important, as well as understanding the potential clinical significance of the antibody and the urgency of transfusion. When a patient's antibody is directed at a high-prevalence antigen, it is important to test siblings in the quest for compatible blood and to urge the patient to donate blood for long-term storage when clinical status permits. In hemolytic anemia due to warm-reactive autoantibodies, compatibility may be difficult to demonstrate. In this scenario, the important issue is to be sure that there are no clinically significant alloantibodies underlying the warm reactive autoantibodies.

Prevention of Alloimmunization

Transfusion management of patients who require chronic transfusion therapy, in particular patients with sickle cell disease, has been the subject of debate.[9-12] Many programs attempt to reduce or prevent alloimmunization by prophylactic transfusion of blood that is antigen-matched for C, E, and K. Some do antigen matching for these antigens and more, once the patient makes an antibody (Table 111-4). No consensus exists at present as to the best approach, although the goal is to prevent hemolytic or delayed transfusion reactions, which are known to be underreported because they can manifest as a sickle cell crisis.

Table 111-4 Approaches to Supplying Red Blood Cell Products to Prevent Alloimmunization in Patients with Sickle Cell Disease or Other Transfusion-Dependent Anemia

Phenotype or genotype for clinically significant antigens before transfusion
Provide phenotype-matched blood for C, E, and K prophylactically
Provide blood negative for the major antigens that the patient lacks after the patient makes an antibody

Blood Group Disease Association

The absence of some blood group antigens and their carrier molecules can result in disease. For example, an absence of the Rh and RhAG proteins causes stomatocytosis[13] and anemia, termed *Rh_{null} syndrome*. The absence of Xk protein is associated with the *McLeod syndrome.* RBCs and white blood cells from patients with leukocyte adhesion deficiency II (also known as *congenital disorder of glycosylation type II*) lack antigens that are dependent on fucose. The RBCs have the Le(a–b–) Bombay phenotype and the white blood cells lack siayl-Le^x, which explains the high white blood cell count and infections in these patients. Hemagglutination is a simple test that can be used to diagnose these syndromes. In patients with paroxysmal nocturnal hemoglobinuria, a proportion of the RBCs will lack antigens carried on GPI-linked proteins. Other associations between blood group antigens and diseases are summarized in Table 111-1.

Diseases associated with antibodies to blood group antigens include hemolytic disease of the newborn, warm autoimmune hemolytic anemia, cold hemagglutinin disease and paroxysmal cold hemoglobinuria. Hemagglutination is a valuable aid in diagnosis of these conditions.

Blood Group Systems

Presented here is a brief description of the most clinically relevant blood group systems in approximate order of clinical significance. For further information and prevalence of blood group antigens in different populations, refer to specialized texts such as *Human Blood Groups*, *The Blood Group Antigen Facts Book,* and the AABB *Technical Manual.*[2,3,14]

Carbohydrate Blood Groups

ABO and H

The ABO blood group system is by far the most clinically significant, because of the presence of naturally occurring IgM antibodies (and sometimes IgG). The original observation by Landsteiner that certain human erythrocyte suspensions were agglutinated by other human sera led to the recognition of ABO polymorphism. This initial observation is still the cornerstone of modern transfusion practice more than a century later.

Antigens and Their Synthesis. ABH antigens occur on glycoproteins and glycolipids and are synthesized in a stepwise fashion by glycosyltransferases that sequentially add specific monosaccharides in specific linkages to a growing oligosaccharide precursor chain (reviewed in Clausen and Hakomori[15]). The terminal sugar

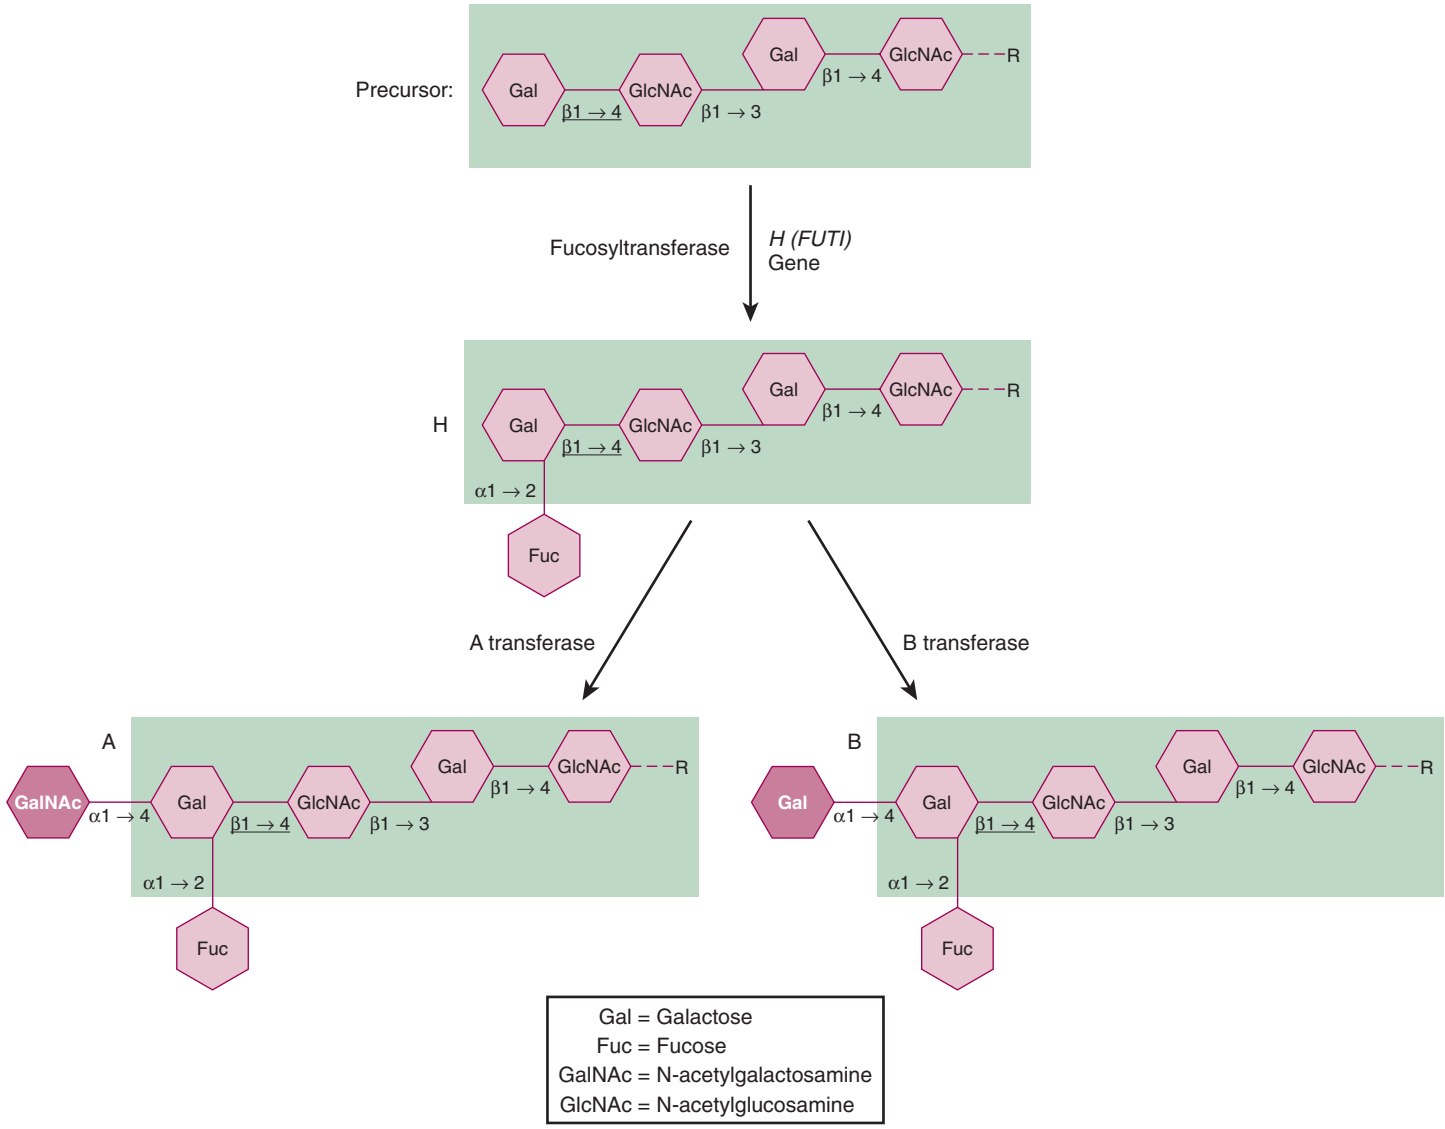

Figure 111-2 BIOCHEMICAL STRUCTURES OF ABH ANTIGENS. Schematic representation of the terminal portions of the carbohydrate structures carrying the H, A, and B antigens on RBCs.

determines antigen specificity (Fig. 111-2). Group O individuals have H antigen only, the terminal sugar of which is fucose, and this is the precursor substrate for A and B antigens. Group O individuals have defective A or B transferases. The A and B transferase enzymes differ only by the nature of the monosaccharide added to the chain. *N*-acetyl-D-galactosamine is added by A-transferase, and D-galactose is added by B-transferase. In clinical practice, four ABO phenotypes (A, B, O, and AB) are discriminated. In addition, two common variations of group A—A_1 and A_2—can be distinguished. The differences between A_1 and A_2 phenotypes are quantitative and qualitative. Not only is the A_1 transferase more efficient in converting H to A antigen (approximately 5 times more A sites per RBC on A_1 RBCs than on A_2 RBCs), it also has the capacity to make A_1 antigen on the repetitive A epitope. Quantitatively normal ABH expression also requires the branching of carbohydrate chains, which is performed by the blood group I enzyme. Some H antigen precursor remains on A and B RBCs in this order: $A_2 > B > A_2B > A_1 > A_1B$.

Inherited and Acquired ABH variants. In addition to the main ABO types, there are many other inherited phenotypes with a weaker expression of the specified antigen, for example, A_3, A_x, A_{el}, B_3, B(A), and cis-AB. This can cause problems in determining the ABO blood group, but for patients needing immediate transfusion, the selection of group O red cells and AB plasma products is an option. In blood donors, if very weak expression of A or B antigens is not detected, the major risk is that the red cells may be transfused to a patient whose antibodies may cause accelerated destruction of the transfused cells.

Rare Bombay (O_h) phenotype RBCs (first reported in Bombay, India) lack H antigen and, consequently, A and B antigens. Other variants with weak H expression on RBCs, with or without H in secretions, also occur (para-Bombay) and have been reviewed.[16] Of clinical relevance, potent anti-H with the same hemolytic potential as anti-A and anti-B can be produced by Bombay individuals. Anti-H is often found in para-Bombay individuals but is generally not a potent antibody. HDFN due to anti-H has not been reported.

Acquired B antigen is a rare phenomenon that results from the action of bacterial deacetylase, an enzyme that can remove an acetyl group from the A-terminal sugar, *N*-acetylgalactosamine. Galactosamine is similar to galactose, the B-specific terminal residue, and anti-B reagents can cross-react with the deacetylated structure. Acquired B can occur in individuals suffering from gram-negative infections of gastrointestinal origin or carcinoma and can be clinically significant if a patient's blood group is misinterpreted and group AB blood is transfused. Other polyagglutinable states (e.g., T, Tn, Tk) are detected by naturally occurring antibodies found in the serum of most people; these can be identified by a panel of lectins.

A or B antigen expression can weaken in patients with acute leukemia or stress hematopoiesis or, occasionally, during pregnancy. Chromosomal deletions or lesions that involve the ABO locus can result in the loss of transferase expression in the leukemic cell population. A decrease in A or B antigen expression, when found without a hematologic disorder, can be prognostic of a preleukemic state.

Genes and Enzymes. The *ABO* gene was cloned in 1990 following purification of A transferase; since then, over 200 different alleles have been described.[17] There are only four amino acid differences between A and B transferases in the catalytic domain, two of which (Leu266Met and Gly268Ala) are primarily responsible for the substrate specificity. The group O phenotype results from mutations in *ABO* that cause a loss of glycosyltransferase activity. The most common group O (O_1) results from a single nucleotide deletion near the 5′ end of the gene that causes a frameshift and early termination with no active enzyme production. The rare B(A) and cis-AB phenotypes express both A and B from a single allele due to variant glycosyltransferases that have a combination of A- and B-specific residues.

The fucosyltransferases required for H synthesis are encoded by two closely linked genes on chromosome 19, *FUT1* (or H) and *FUT2* (or *Se* for secretor), which have different substrate specificity and expression in tissues. Homozygosity for defective *FUT2* alleles is responsible for the common nonsecretor phenotype in which A, B, and/or H antigen are not present in secretions. Individuals homozygous for null alleles at both the *FUT1* and *FUT2* loci have the Bombay phenotype (see earlier section).

ABO and Transplantation. As tissue antigens, ABO antigens are important in solid organ transplantation. Recipient antibodies will react with antigens on the transplanted organ, and complement activation at the surface of endothelial cells can result in rapid destruction and hyperacute rejection. However, successful transplantation across ABO barriers is possible, particularly with blood group A_2 to O and with current immunosuppressive and pretreatment regiments including removal of ABO antibodies.[18] Allogeneic hematopoietic stem cell transplantations are routinely performed regardless of ABO compatibility, but occasionally initial hemolysis or pure red cell anemia due to persisting anti-A or anti-B titers in the recipient can result.

Antibodies. Anti-A and anti-B are found in the sera of individuals who lack the corresponding antigens. They are produced in response to environmental stimulants, such as bacteria. These antibodies are produced after birth, reaching a peak at 5 to 10 years of age, and declining with increasing age. The antibodies are mostly IgM and can activate complement, which in conjunction with the high density of ABO antigen sites on RBCs, are responsible for the severe, life-threatening transfusion reactions that may result following ABO-incompatible transfusions. In contrast, HDFN caused by ABO antibodies is usually mild because (1) placental transfer is limited to the fraction of IgG anti-A and anti-B found in maternal serum, (2) ABH antigens are not fully developed on fetal RBCs because of a lack of fully branched carbohydrate chains, and (3) tissue ABH antigens provide additional targets for the antibodies.

Platelets have intrinsic A, B, and H antigens; thus ABO incompatibility can decrease the post-transfusion platelet increment, but this is usually not of clinical significance.[19] However, platelets from donors with an A_2 phenotype lack both A and H antigens. Approximately 20% of group A platelets would be from A_2 donors and would be appropriate for "universal" use. Platelets from A_2 donors may also be a superior product for patients undergoing A/O major mismatch allogeneic progenitor cell transplantation.[17]

Potent anti-H (along with anti-A and anti-B) found in O_h (Bombay) individuals will destroy transfused RBCs of any ABO group, so these individuals must be transfused only with H– RBCs. In contrast, anti-H identified in individuals with low expression of H antigen, notably A_1B and A_1, is usually IgM, reacts only at lower temperatures, and is thus clinically insignificant.

Other Carbohydrate Blood Group Systems

As for all glycoconjugate structures, sequential enzymatic action is required to build other carbohydrate antigenic epitopes, and the genetic background of all these involves different glycosyltransferase loci.

The null p phenotype, P_2^k and P_1^k, are of clinical interest because of potent naturally occurring antibodies that are present in plasma of individuals whose RBCs lack the glycolipid-based antigens P1/P/P^k, P1/P or P, respectively. In analogy with the ABO blood group system, antibodies of IgM and IgG class (anti-PP1P^k, anti-P1P, or anti-P) are made against the missing antigens. Although the incidence of the null phenotypes is only 5 to 10 per million, they have attracted considerable interest because of their relationship to disease and as receptors for pathogens. Women with p and P^k phenotypes suffer a high incidence of spontaneous abortion, a phenomenon most likely due to destruction of the placenta by anti-P. Additionally, anti-P and anti-P^k cause hemolytic transfusion reactions if antigen-positive RBCs are transfused. Transient autoanti-P, produced following a viral infection, causes paroxysmal cold hemoglobinuria and lysis of autologous P-positive RBC. P antigen (also known as *globoside*) is the cellular receptor for parvo-B19 virus that causes erythema infectiosum (fifth disease) in children, sometimes complicated by severe aplastic anemia due to lysis of early erythroid precursors. P-fimbriated *Escherichia coli* expresses both P- and P^k-binding molecules at the tips of their pili, a finding with implications for uropathogenicity. Individuals lacking P, or P^k and P, appear to be naturally resistant to these bacterial and viral infections. In contrast to anti-P and anti-P^k, it should be noted that anti-P1 is a cold-reactive agglutinin that seldom has clinical importance.

Lewis antigens are fucosylated glycolipids that are synthesized by nonerythroid cells, circulate in plasma, and are passively adsorbed onto RBC. Antibodies to Lewis can be made by individuals with the Le(a–b–) phenotype. These antibodies are of IgM class and seldom cause any clinical problems but are commonly found in pregnant women.

The i and I antigens are nonterminal epitopes on linear and branched carbohydrate structures, respectively, carrying ABH antigens at their terminal ends. During the first years of life, linear chains are modified into branched chains, resulting in the appearance of I antigens. The i phenotype is very rare among adults, but it is the normal state on RBCs from fetuses and infants. The gene encoding the I-branching β-1,6-*N*-acetylglucosaminyltransferase (GCNT2) has three alternative forms of exon 1 with common exons 2 and 3. Mutations in exon 2 or exon 3 silence *GCNT2* and give rise to the form of the i phenotype that is associated with cataracts in Asians. Mutations in exon 1C silence the gene in erythrocytes (but not in other tissues) and lead to the i phenotype without cataracts.

Alloanti-I made by a person with the rare i adult phenotype can be clinically significant and cause destruction of transfused I-positive RBCs. However, the sera of all I-positive individuals contain autoanti-I that is clinically benign and reactive only at or below room temperature. In contrast, cold hemagglutinin disease is characterized by a high titer of complement-fixing monoclonal anti-I, which causes in vivo hemolysis and hemolytic anemia. The titer and thermal range of autoanti-I is often increased following infection with *Mycoplasma pneumoniae*. If transfusion cannot be avoided, donor RBCs should be transfused through a blood warmer.

Protein Blood Groups

Rh, RhAG, and LW Blood Group Systems

The Rh system is second only to the ABO system in importance in transfusion medicine. Rh antigens, especially D, are highly immunogenic; thus in most countries, blood for transfusion is tested and labeled with the D antigen type (Rh-positive or Rh-negative) and D– recipients are transfused with D– RBC products.

Three systems for naming Rh antigens have been used. Two are shown in Table 111-5, which indicates the incidence of the common

Rh haplotypes present in different ethnic groups. The Fisher-Race nomenclature was based on the premise that there were three closely linked genes (D, C/c, and E/e), whereas the Wiener nomenclature (Rh-Hr) was based on the belief that a single gene encoded multiple factors (antigens). Although it is now well-established that two genes, *RHD* and *RHCE,* encode the Rh proteins, the Fisher-Race (D, C/c, and E/e) terminology is often preferred for written communication; for spoken communication, a modified version of the Wiener nomenclature is preferred. Uppercase *R* indicates that D antigen is present and use of a lowercase *r* (or "little r") indicates that it is absent. The C or c and E or e antigens carried with D are represented by subscripts: 1 for Ce (R_1), 2 for cE (R_2), 0 for ce (R_0), and Z for CE (R_z). The presence of these antigens without D is represented by a superscript: prime for Ce (r'), double-prime for cE (r''), and y for CE (r^y). This terminology allows one to convey the common Rh antigens (the phenotype) with a single term. The third system of numeric designations is not widely used in the laboratory, with a few exceptions (Rh17, Rh32, Rh33).

Genes, Proteins, Antigens, and Phenotypes. The Rh proteins are designated RhD (encoded by *RHD*), which carries the D antigen, and RhCE (encoded by *RHCE*), which carries the CE antigens (either ce, cE, Ce, or CE). RhD differs from the various forms of RhCE by 32 to 35 amino acids. RhD and RhCE are not glycosylated but form a complex in the RBC membrane with RhAG (Rh-associated glycoprotein). Other proteins present in the Rh-complex are CD47 (an integrin-associated protein), LW, and glycophorin B. The Rh-complex also associates with band 3 (the anion exchanger) as a macro-complex in the membrane.

The D-negative (Rh-negative) phenotype is prevalent in whites (15%-17%), less likely in African Blacks (3%-5%), and rare in Asians (<0.1%). The absence of D in Europeans is due primarily to a deletion of the *RHD* gene. African Blacks and rare D-negative whites and Asians carry a *RHD* gene that is silenced by a variety of molecular events.[3]

RBCs with weak D have D antigen but at lower levels than normal because of one or more amino acid changes that are often predicted to be in the intracellular or transmembrane regions of RhD. The majority of individuals with a weak D phenotype can safely receive D-positive blood and do not make anti-D.[18]

Partial D antigens (previously called *D categories* or *D mosaics*) are caused either by point mutations in *RHD*, resulting in amino acid changes that alter D epitopes, or by replacement of *RHD* nucleotides or exons by the equivalent part of *RHCE.* RBCs with a partial D antigen may have strong or weak expression of the D antigen but have altered or missing D epitopes. Because patients with partial D antigens can make anti-D to the D epitopes they lack, they ideally should receive D-negative blood and women of childbearing potential are candidates for Rh immune globulin. In practice, most type as D-positive and are recognized only after they make anti-D. Some monoclonal D typing reagents can classify some partial D phenotypes as D negative (partial DVI) in direct testing. *RHD* genotyping is very useful to distinguish partial D in order to prevent D alloimmunization and to avoid unnecessary Rh immune globulin injection (see box on Weak or Variable D Typing).

Several phenotypes, including D– –, Dc– and DC^w–, have an enhanced expression of D antigen and no, or variant, CE antigens. They are caused by replacement of portions of *RHCE* by *RHD*. The RhD sequences in RhCE, along with a normal RhD, explain the enhanced D and account for the lack, or reduced expression, of CE antigens. Immunized individuals with these CE-depleted phenotypes can make antibodies to high-prevalence Rh antigens.

C and c antigens differ by four amino acids, but only residue Ser103Pro is predicted to be extracellular. E and e differ by one amino acid, Pro226Ala. The RhD and various combinations of RhCE proteins (ce, Ce, cE, and CE) are typical for the majority of white transfusion recipients. However, Rh proteins in other ethnic groups often carry additional polymorphisms, particularly in individuals of African descent, and this fact often complicates transfusion in patients with sickle cell disease. For example, the RBCs of more than 30% of blacks are VS+ because of a Leu245Val substitution in Rhce, and expression of this antigen is associated with variant expression of e antigen. Many other amino acid changes in Rhce, as well as in RhD, are associated with production of Rh antibodies in patients with sickle cell disease. RH genotyping by DNA methods allows enhanced Rh antigen matching of patients and donors and is particularly important in patients who present with Rh antibodies reacting with all, or the majority, of cells tested.

The Rh_{null} phenotype is very rare and occurs on two genetic backgrounds: the "regulator" type, caused by mutations in RHAG, which encodes Rh-associated glycoprotein, and the "amorph" type, caused by mutations in *RHCE* on a D- (deleted *RHD*) background. Rh_{null} RBCs are stomatocytic, fragile, and associated with anemia.

Antibodies. Most Rh antibodies are IgG and do not activate complement. As a result, primarily extravascular hemolysis, rather than intravascular hemolysis, occurs in transfusion reactions involving Rh antibodies. The antibodies are almost always due to RBC immunization from pregnancy or transfusion and usually persist for years. Anti-D can cause severe transfusion reactions and HDFN, but the incidence of anti-D has decreased with the prophylactic use of Rh immune globulin. Most Rh antibodies should be considered as having the potential to be clinical significant for HDFN and transfusion reactions. If serum antibody levels fall below detectable levels, subsequent exposure to the antigen characteristically produces a rapid secondary immune response. Autoantibodies in the sera of patients

Table 111-5 Prevalence of the principal Rh Haplotypes

Fisher-Race Haplotype	Modified Weiner Haplotype	Incidence (%)		
		White	African Black	Asian
Rh-POSITIVE				
DCe	R_1	42	17	70
DcE	R_2	14	11	21
Dce	R_0	4	44	3
DCE	R_z	<0.01	<0.01	1
Rh-NEGATIVE				
ce	r	37	26	3
Ce	r'	2	2	2
cE	r''	1	<0.01	<0.01
CE	r^y	<0.01	<0.01	<0.01

Weak or Variable D Typing

Clinically significant D sensitization potentially results in a pregnancy with a fetus at risk for hemolytic disease of the fetus and newborn and hemolytic transfusion reactions if transfused with D-positive RBCs. Individuals with RBCs that express a partial D antigen are at risk for D-sensitization, whereas those with weak D antigen are usually not at risk. These cannot be distinguished by serologic reactivity, because either may present as weak or moderately positive or give variable results with anti-D reagents. Particularly in the prenatal setting, RHD genotyping should be done to distinguish weak D from partial D. Women with weak D expression are not at risk for clinically significant D sensitization and therefore are not candidates for RhIG prophylaxis. In contrast, individuals with partial D lack D epitopes and have produced clinically significant anti-D and should receive RhIG prophylaxis. RHD genotyping avoids unnecessary treatment with RhIG in women with weak D antigen.

with warm autoimmune hemolytic anemia (AIHA), as well as in some cases of drug-induced autoimmune hemolytic anemia, appear to demonstrate relative specificity to high-prevalence Rh antigens, although other members of the Rh complex have not been ruled out (see box on Transfusion Management of Patients With Warm Autoimmune Hemolytic Anemia).

RHAG Blood Group System

RhAG glycoprotein, encoded by *RHAG,* is highly similar to the RhD and RhCE proteins. It carries four blood group antigens: two of high prevalence (RHAG1 and 3) and two of low prevalence (RHAG 2 and 4). Antibodies to RHAG4 cause HDFN. RhAG is important for erythrocyte ion balance in RBCs and is required for the expression of RhD and RhCE proteins forming the core of the Rh-complex.

Transfusion Management of Patients With Warm Autoimmune Hemolytic Anemia

Patients with warm autoimmune hemolytic anemia may present with jaundice, fatigue, and anemia, or they may show no overt clinical manifestations. The antibody screen and antibody identification panel will show all RBCs positive (panagglutinin) with anti-IgG in the indirect antiglobulin test. The autocontrol (patient's own plasma and RBCs) will also be positive.

History: A transfusion history should be obtained to differentiate these results from a hemolytic transfusion reaction or hemolysis due to an alloantibody.

DAT: A direct antiglobulin test should be performed with anti-IgG and -C3. In clinically significant hemolysis, the DAT is usually strongly positive.

Eluate: If patient has been recently transfused (3-4 months), an eluate should be prepared from the patient cells to remove the antibody(ies); the eluate should be tested to determine specificity. The eluate is usually reactive with all cells when tested by the IAT with anti-IgG.

Phenotype: Type the patient's RBCs for minor blood group antigens (Cc, Ee, K, Jka/b, Fya/b, Ss) if the patient has not been recently transfused. When possible, IgM typing reagents are used because the patient's own antibody-coated RBCs may result in false-positive typing. Some laboratories are able to remove the IgG from the RBCs and perform a phenotype. Alternatively, genotyping for minor blood group antigens including $Do^{a/b}$ antigens (there is no serologic reagent) can be performed.

Adsorption: Adsorb the serum autoantibody onto the patient's own RBCs to test for underlying alloantibody if the patient has not been recently transfused (3-4 months). If the patient has been recently transfused or if the low hematocrit results in insufficient autologous RBCs, perform alloadsorption with well-characterized RBCs (usually three with known antigen profiles). Test the adsorbed serum for underlying alloantibodies.

Crossmatch: Perform with neat and with adsorbed plasma. Crossmatch performed with neat plasma will usually be incompatible.

Communication: Inform ordering physician of reactivity and of delay in receiving crossmatched RBCs. Provide emergency-release RBCs if patient's clinical situation warrants. Inform the physician that the patient may hemolyze transfused RBCs similar to hemolysis of his or her own RBCs.

Transfusion: Consider providing RBC units negative for minor antigens that the patient also lacks (consider matching for Cc, Ee, K, Jka/b, Fya/b, Ss). This potentially enables RBC units to be available before completion of the antibody identification testing. Transfusion with antigen matched units potentially allows continued transfusion without need for auto- or alloadsorption unless signs and symptoms of RBC destruction occur or there is a change in reactivity in antibody screening or the DAT.

LW Blood Group System

Rh and LW are independent blood group systems but have a phenotypic relationship. In adults, D-positive RBCs have a stronger expression of LW antigen than D-negative RBCs, and anti-LW can be confused with anti-D. Transient loss of LW antigens from RBCs has been described in pregnancy and in patients with diseases, particularly Hodgkin's disease, lymphoma, leukemia, sarcoma, and other forms of malignancy. Loss of LW antigens is usually associated with the production of antibodies that appear to be alloanti-LW.

Kell and Kx Systems

The Kell glycoprotein is highly folded through multiple intrachain disulfide bonds and is covalently linked to XK protein in the RBC membrane. Kell is highly polymorphic due to single amino acid substitutions in the glycoprotein that account for 33 of 34 antigens described to date. The K antigen is remarkably immunogenic for differing from wild-type (small k) by only one amino acid, and it appears that loss of an N-glycan exposes the peptide, thereby rendering it immunogenic.

Inherited weak expression of Kell antigens occurs with amino acid changes in the protein, termed K_{mod} phenotype, and occurs with Kp^a in cis, and in the McLeod phenotype.[19] Transient depression of Kell system antigens occurs in autoimmune hemolytic anemia, in microbial infections, and in two cases of idiopathic thrombocytopenia purpura. The lack of Kell antigens (the K_0 or K_{null} phenotype) is caused by several different gene defects.

HDFN due to anti-K can result in severe neonatal anemia, and unlike anti-D, maternal antibody titers and amniotic bilirubin levels are not good predictors of the severity of the disease. Kell antigens are expressed very early during erythropoiesis, and anti-K has been shown to suppress erythropoiesis in vitro. This may explain the low level of bilirubin observed in cases of neonatal anemia; thus Doppler screening of the fetal middle cerebral artery peak systolic velocity is used to monitor anemia. Other unusual consequences of Kell antibodies include risk for fetal thrombocytopenia and neutropenia.

McLeod Syndrome. This uncommon syndrome is associated with the loss of expression of Kx protein due to mutations and deletions in the *XK* gene.[20,21] The syndrome, which is X-linked and manifests only in males, may be underdiagnosed. The physical characteristics, which often develop only after the fourth decade of life, include muscular and neurologic problems. A minority of patients with chronic granulomatous disease (CGD) also have the McLeod phenotype as a result of X-chromosome deletions encompassing both genes. Carrier females have two populations of RBCs (one of the McLeod phenotype and one of normal phenotype).

Duffy Blood Group System

The Duffy (FY) glycoprotein is a promiscuous chemokine receptor found on RBCs and on endothelial cells in the kidney and brain that binds a family of chemotactic and proinflammatory peptides from the CXC (IL-8, MGSA) and the CC (RANTES, MCP-1, MIP-1) classes. The physiologic role of FY is clear, but on RBCs the receptor may allow RBCs to act as scavengers for excess chemokines. FY is also a receptor to which *Plasmodium vivax* merozoites can bind to invade RBC and cause malaria.

Antigens. The Fy^a and Fy^b antigens differ by a single amino acid (Gly42Asp) located on the N-terminal extracellular domain of the FY glycoprotein and is responsible for the common Fy(a+b–), Fy(a–b+) and Fy(a+b+) phenotypes. The null Fy(a–b–) phenotype is rare in

most ethnic groups, but it is common in people of African and Arabian origins. The null phenotype most often results from a mutation in the promoter region of *FY* that disrupts a binding site for the erythroid transcription factor GATA-1 and results in loss of FY on RBCs.[22] Because the erythroid promoter controls expression only in erythroid cells, FY expression in other tissues is unaffected. All individuals of African origin with a mutated GATA box to date have been shown to carry *FYB* and therefore Fy^b is expressed on nonerythroid tissues. This explains why Fy(a–b–) individuals make anti-Fy^a but not anti-Fy^b. Fy(a–b–) due to a mutated GATA box on an *FYA* allele has been found in Papua New Guinea, another malaria-endemic region.

Antibodies. FY antigens are much less immunogenic than Rh and K. Anti-Fy^b is less common than anti-Fy^a, and both antibodies can cause DHTR and rarely HDFN. Anti-Fy3 is made by Fy(a–b–) individuals who may lack FY protein on all cells.

Kidd Blood Group System

The Kidd (JK) blood group protein was implicated in urea transport when RBCs lacking the antigens were shown to resist lysis in 2 M urea. The protein is present in RBCs and kidney medulla and is a constitutive urea transporter, but failure to express Kidd does not result in an overt clinical syndrome; the only observed manifestation is a reduced capacity to concentrate urine.[23]

Antigens. The Jk^a and Jk^b antigens differ by a single amino acid (Asp280Asn) and are responsible for the common Jk(a+b–), Jk(a–b+) and Jk(a+b+) phenotypes. The Jk(a–b–) or Jk_{null} phenotype is uncommon and occurs with greater incidence in Polynesians, Asians, and Finns. The silent alleles in Polynesians/Asians have splice-site or missense mutations in *JKB* alleles that abolish expression of Jk^b, and large deletions and premature stop codons in *JKA* alleles have been found in Caucasian Jk_{null} pedigrees. Weakly expressed variants of Jk^a and Jk^b antigen are found.

Antibodies. JK antibodies are responsible for at least one-third of cases of delayed hemolytic transfusion reactions. The antibodies often drop to undetectable levels or react only with cells that are homozygous for the antigen and escape detection in the sensitized patient's serum before transfusion. JK antibodies only rarely cause HDFN, and if they do, it is typically not severe. Anti-Jk3, sometimes referred to as anti-Jk^{ab}, is produced by Jk(a–b–) individuals, and rare donors must be located for transfusion.

MNS System

M and N antigens are carried on alternative forms of glycophorin A (GPA), whereas S and s antigens are carried on alternative forms of glycophorin B (GPB). M/N and S/s are homologous proteins encoded by adjacent genes and consequently show linkage disequilibrium in inheritance of the antigens. The MNS system is highly polymorphic and most of the 46 antigens are the result of amino acid substitutions or rearrangements between *GYPA* and *GYPB*. Persons who are S–s– are usually of African origin who also lack the high-prevalence U antigen due to a deletion of *GYPB* or express variant weak U antigen as a result of an altered form of *GYPB*.

Antibodies. Anti-S, -s, and -U are usually IgG and can be clinically significant antibodies. Anti-M and anti-N can be naturally occurring, may be reactive at room temperature or below, and are often clinically insignificant.

Other Protein Antigens

Antibodies to antigens in the following systems are less common than those described earlier in this chapter, and information regarding their general clinical significance is summarized in Table 111-3.

Lutheran System

Lutheran (Lu), along with Secretor, provided the first example of autosomal linkage in humans, the first example of autosomal crossing over, and the first indication that crossing over in humans is more common in females than in males. The Lutheran system consists of four antithetical pairs of antigens and 12 independent high-prevalence antigens. The Lu(a–b–) phenotype is rare, but in the majority of individuals, it is due to heterozygosity for silencing mutations in the *EKLF/KLF1* gene.[24] KLF1 is a transcription factor that regulates many erythroid-specific genes, and the expression of antigens in other blood group systems (e.g., Knops, Indian) is also affected.

Antibodies. Antibodies in this system are rarely encountered because the antigens are not highly immunogenic. They are usually IgG and give characteristic agglutinates surrounded by unagglutinated RBCs. They can cause mild transfusion reactions, but do not typically cause HDFN. Anti-Lu3 is found in the serum of immunized people of the rare recessive Lu(a–b–) phenotype, and the antibody is usually IgG and may cause a delayed transfusion reaction or HDFN. Blood with the Lu(a–b–) phenotype should be used for transfusion of patients with these antibodies.

Diego System

The Diego (Di) blood group antigens are on band 3, the red cell anion exchanger (AE1), one of the most abundant erythrocyte glycoproteins. Band 3 forms complexes with many other proteins in the cell membrane and is important for RBC stability. The Diego blood group system contains 2 antithetical pairs of antigens and 18 low-prevalence antigens. Di^b antigen has a prevalence of greater than 99.9%, but Di^a is rare in most populations. Exceptions include South American Indians (Di^a occurs in 54% of this population) and North American Indians, approximately 12% of whom are Di(a+).

Antibodies. Diego antibodies are usually IgG and do not bind complement. These antibodies have caused transfusion reactions (usually delayed) and HDFN. Autoantibodies to band 3 are common in patients with warm autoimmune hemolytic anemia.

Yt Blood Group System

The Yt system was named in 1956 when an antibody was found in the serum of patient whose last name was Cartwright. Yt^a occurs with a prevalence of more than 99% in random blood samples, and Yt^b is found with a prevalence of approximately 8%, except in Israelis, in whom it has a prevalence of 20% or higher.

Antibodies. Yt antibodies usually are IgG and do not bind complement. These antibodies have caused delayed transfusion reactions but not HDFN.

Scianna Blood Group System

The Scianna (Sc) antigens are expressed by the RBC adhesion protein, erythrocyte membrane-associated protein (ERMAP). Sc1 is a high-prevalence antigen (prevalence ≈99.9%), and Sc2 is a low-prevalence antigen (1%); there are five other Scianna antigens.

Antibodies. Scianna antibodies are usually IgG, and some bind complement. These antibodies have not caused transfusion reactions, and although they have caused a positive DAT in cord RBCs, they have not caused HDFN. Several examples of autoanti-Sc1 have been reported, some reactive in tests using patient serum but not plasma. Autoanti-Sc3–like antibodies have been described in one patient with lymphoma and in one patient with Hodgkins disease whose RBCs had suppressed Sc antigens.[2]

Dombrock Blood Group System

Dombrock (Do) antigens are carried on a GPI-linked glycoprotein that is a member of the mono-ADP-ribosyltransferase family (ART4), although Do has no demonstrable enzyme activity on the RBC. The Dombrock blood group system consists of two antithetical antigens, Do^a and Do^b, and six other antigens of high prevalence. The null phenotype is Gy(a–).

Antibodies. Do^a and Do^b antigens are poor immunogens, and anti-Do^a and anti-Do^b are rarely found as single specificities. Antibodies in the Do system are usually IgG and do not bind complement. These antibodies have caused delayed transfusion reactions and a positive DAT but no clinical HDFN.

Colton Blood Group System

The Colton antigens are carried on aquaporin-1 (AQP-1), the first water channel protein characterized in mammals, and are also found in the kidney. The function of AQP-1 in RBCs may be to rehydrate rapidly after shrinking in the hypertonic environment of the renal medulla. Co^a has a prevalence of 99.9%, its antithetical antigen Co^b has a prevalence of 10%, and Co3 and Co4 are present on all RBCs except those of the very rare Co(a–b–) null phenotype. Apparently healthy propositi with the Co(a–b–) phenotype and AQP-1 deficiency have RBCs with an 80% reduction in the ability to transport water. The residual water transport in these RBCs may be through another member of the water channel protein family, AQP-3, which transports water, glycerol, and urea, and carries the blood group antigen GIL.

Antibodies. Antibodies in the Colton system are usually IgG and some bind complement. The antibodies have caused delayed transfusion reactions and HDFN.

Gerbich Blood Group System

The Gerbich system antigens are carried on glycophorin C (GPC) and glycophorin D (GPD). There are six high-prevalence antigens and five low-prevalence antigens. The two glycoproteins are products of the *GYPC* gene. The gene consists of four exons, and the smaller GPD is generated by the use of an alternative translation initiation site.

Antibodies. The antibodies may be immune or naturally occurring. Most are IgG, and some of these bind complement. Some antibodies may be IgM. Although some antibodies have caused delayed transfusion reactions, others have been benign. Clinical HDFN has not been reported, but the antibodies have been eluted from DAT-positive cord RBCs.

Cromer Blood Group System

The Cromer antigens are carried on decay-accelerating factor (DAF, CD55), a complement control protein attached to the RBC membrane through GPI-linkage. Cromer is a system of two sets of antithetical antigens (Tc^a/Tc^b/Tc^c and WES^a/ WES^b), 13 high-prevalence antigens, and three low-prevalence antigens. The Cr(a–) phenotype is the least rare of the negative phenotypes, and with the exception of one Spanish-American woman, all people with Cr(a–) RBCs are black. Most of the other phenotypes are exceedingly rare.

Antibodies. Antibodies in the Cromer system are usually IgG and do not bind complement. The antibodies have caused mild delayed transfusion reactions but not HDFN.

Knops Blood Group System

The Knops blood group antigens are carried on complement receptor 1 (CR1). Kn^a, Sl^a, and McC^a antigens are fairly common and have a similar prevalence (>90%) in different populations; however, Sl^a is present on RBCs of 98% of whites, but on only 60% of African Americans. Typing for Knops system antigens can be challenging because of the low level of expression on the RBCs in some disease processes gives false-negative results. RBC CR1 is important in the processing of immune complexes, binding them for transport to the liver and spleen for removal from the circulation. The CR1 copy number per RBC (and thus antigen strength) is reduced in SLE, cold agglutinin disease (CAD), PNH, hemolytic anemia, insulin-dependent diabetes mellitus, acquired immunodeficiency syndrome, some malignant tumors, and any condition associated with increased clearance of immune complexes. CR1 (the Sl^a antigen in particular) may act as a receptor for the malarial parasite *Plasmodium falciparum*; thus the Sl(a–) phenotype may provide selective advantage.[25]

Antibodies. Antibodies in the Knops system are usually IgG, and they do not bind complement. The antibodies do not cause transfusion reactions or HDFN, and once identified, they can usually be ignored for clinical purposes. Identification may be complicated by the fluctuation of antigen expression on RBCs. In the Knops system, anti-Kn^a is the most common antibody in whites, and anti-Sl^a is the most common in African Americans.

Indian Blood Group System

The antigens of the Indian system are carried on CD44. CD44 has a diverse range of biologic functions involving cell-cell and cell-matrix interactions in cells other than RBCs. It is an adhesion molecule in lymphocytes, monocytes, and some tumor cells. CD44 binds to hyaluronate and other components of the extracellular matrix and is also involved in immune stimulation, as well as signaling between cells.[26] In^b is a common antigen, and In^a is rare in white persons but has a prevalence of 4% in Indians, 10% in Iranians, and nearly 12% in Arabs.

Antibodies. Antibodies in the Indian system are usually IgG and do not bind complement. Some antibodies may directly agglutinate RBCs, but the reactivity is greatly enhanced by the IAT. These antibodies have caused decreased RBC survival and a positive DAT in the neonate but not HDFN. A severe, delayed, hemolytic transfusion reaction due to anti-In^b has been reported.

Chido/Rodgers Blood Group System

Although the Ch and Rg antigens are readily detected on RBCs, they are located on the fourth component of complement (C4), which becomes bound to RBCs from the plasma. In complement activation through the classical pathway, C4 becomes bound to the RBC membrane and undergoes further cleavage; ultimately, a tryptic fragment, C4d, remains on the RBC. This C4d glycoprotein carries the Ch/Rg blood group antigens. The antigens are stable in stored serum or plasma, and the phenotypes of this system are most accurately defined in plasma by agglutination inhibition tests.

Antibodies. Antibodies in the Ch/Rg system are usually IgG, do not activate complement, and are considered benign. Considerable variation may be common in the reaction strength obtained with different RBC samples. Although these antibodies do not generally cause transfusion reactions, they have caused anaphylactic reactions.[27] The antibodies have not caused HDFN.

CHAPTER 112

PRINCIPLES OF RED BLOOD CELL TRANSFUSION

Melissa M. Cushing and Paul M. Ness

The clinical practice of transfusion medicine has evolved substantially since the discovery of the ABO system around 1900. Two technologic advances set the stage for clinical practice through blood component therapy. First, the introduction of a safe and effective anticoagulant-preservative solution (suggested by Loutit and Mollison) allowed for the preservation of blood products. Second, in the mid-1960s, the introduction of plastic blood bags by Walter and Murphy, combined with the ability to store blood for extended periods, created opportunities to use transfusions in varied clinical settings. With these discoveries, the era of modern component therapy began. Today, approximately 15 million units of blood are transfused each year in the United States; whole blood transfusions account for only 0.03% of total transfusions. This chapter reviews component therapy, appropriate red blood cell (RBC) transfusion practice in a variety of clinical settings, the clinical implications of red blood cell storage, and existing and emerging alternatives to allogeneic red blood cell transfusions.

RED BLOOD CELL COMPONENTS

Modern transfusion medicine practice aims at providing the specific component of the blood required, rather than whole blood: red cells for oxygen-carrying capacity, plasma for coagulation proteins, and platelets for microvascular bleeding. The component therapy approach allows for optimal use of a limited community resource. Today, the clinician wishing to increase the patient's oxygen-carrying capacity is more likely to use a red blood cell concentrate than whole blood, although there may still be situations in which whole blood, if available, is appropriate. For particular clinical applications, several modifications can be made to red blood cell products to render them depleted of leukocytes or plasma. Red blood cells can also be frozen for long-term storage (Table 112-1).

Whole Blood

A unit of whole blood is collected in CPDA-1 anticoagulant, giving it a shelf life of 35 days and a volume of approximately 510 mL (450 mL of blood plus 63 mL of CPDA-1). Within 24 hours of collection, the platelets and granulocytes are dysfunctional, and several plasma coagulation factors have fallen.

Whole blood has the advantage of correcting simultaneous deficits in oxygen-carrying capacity and blood volume. Therefore whole blood is useful in the management of trauma or in surgical cases involving extensive blood loss. In this setting, whole blood has two distinct advantages: (a) it provides colloid osmotic pressure and coagulation factors not supplied by crystalloid solutions and (b) it does not expose the recipient to red blood cells and plasma from different donors.

The goal of using whole blood for all cases of concomitant red blood cell and volume deficit is difficult to achieve in practice. Most indications for whole blood transfusion are now well managed exclusively with blood component therapy, but the use of fresh whole blood has persisted in military settings. In the civilian setting, the simultaneous need for volume and oxygen-carrying capacity can usually be met by combining red cells with crystalloid or colloid solutions. In some cases of trauma and cardiovascular surgery, platelet transfusion may be indicated to combat microvascular bleeding from dilutional thrombocytopenia or bypass-associated platelet dysfunction. The transfusion of platelets usually supplies the equivalent of several units of relatively fresh plasma so that there is often no reason for further donor exposure by the administration of thawed plasma.

There has been recent renewed interest in fresh whole blood for patients with severe coagulopathy and shock. Few prospective trials have compared fresh whole blood to component therapy. The potential advantages of fresh whole blood when compared with component therapy are a relative increase in hemoglobin (Hb) concentration, coagulation factors, and platelets. In addition, fresh products avoid all of the negative effects of storage and processing. However, fresh whole blood is often not leukoreduced or irradiated. Furthermore, the completion of standard infectious disease testing before transfusion may not be possible within the time frame. Published randomized controlled studies of fresh whole blood in adults are lacking, but research is underway to determine potential indications and optimal storage temperature and duration.

Red Blood Cells

Red blood cells (also referred to as *packed red blood cells* or *red blood cell concentrates*) are obtained from whole blood after removal of most of the plasma for the production of frozen plasma or platelets, or both. At most blood centers, the red blood cells are then mixed with 100 mL of an additive nutrient solution that extends the storage period to 42 days and results in flow properties similar to those of whole blood.

Red blood cells are the product of choice for the correction of an isolated defect in oxygen-carrying capacity, as in cases of chronic anemia. In addition, red blood cells rather than whole blood are used for the emergent transfusion of patients of unknown ABO type. Concentrated group O red blood cells are transfused after the plasma containing isohemagglutinins is removed to prevent potential hemolysis of the recipient's red blood cells.

Leukocyte-Reduced Red Blood Cells

Leukocyte-reduced red blood cells (LRRCs) can be prepared by a variety of methods, resulting in differing degrees of white blood cell removal. Early techniques of preparation involved centrifugation or washing with saline, whereby the buffy coat was repeatedly removed. Currently, the most widely used method of leukoreduction is filtration, which can be performed either in the laboratory or at the bedside. The various filters on the market result in greater than 99% leukocyte reduction while depleting less than 10% of the red blood cells. Blood bags with in-line filters allow prestorage leukoreduction.

The major indication for the use of LRRCs is the prevention of the febrile nonhemolytic transfusion reaction, the most common adverse effect of transfusion, particularly in multiply transfused

Table 112-1 Red Blood Cell Components: Characteristics and Indications

Component	Characteristics	Indications
Whole blood	High volume; good flow	Combined red cell/volume deficit (massive hemorrhage; exchange transfusion)
Red blood cells	Lower volume Higher hematocrit	Red cell deficit
Leukocyte-reduced red blood cells	Good flow in AS	Prevention of febrile reactions Reduction of alloimmunization Reduction of immunomodulatory effects
Washed red blood cells	Plasma depletion Must use within 24 hours	Prevention of severe allergic reactions Prevention of anaphylaxis in IgA deficiency
Frozen red blood cells	Long-term storage Plasma and leukocyte depletion Must use within 24 hours of thawing	Rare donor unit storage Autologous storage for postponed surgery

patients or multiparous females. These reactions are believed to be mediated by antibodies directed against leukocyte antigens (HLA or granulocyte-specific antigens). Depletion of leukocytes to less than 5×10^6 has been shown to prevent, or at least ameliorate, such reactions in most patients. Increasing evidence suggests that cytokines play a role in causing these reactions. Because cytokines may be released from leukocytes during storage, prestorage leukoreduction procedures are the preferred mode of leukoreduction.

A second important indication for LRRCs is the prevention of alloimmunization to HLA antigens that can adversely affect posttransfusion platelet increments, such as in oncology patients undergoing chemotherapy. This approach will be effective only if leukoreduced platelets are also used. According to current AABB standards, the total leukocyte number must be less than 5×10^6 when intended for this purpose. With the introduction of third-generation leukoreduction filters for both red blood cells and platelets, this goal is achievable. A multicenter study known as TRAP showed that the use of leukoreduction filters for platelet products significantly decreased the rate of alloimmunization, but did not completely eliminate the problem.

A third indication for the use of LRRCs is to prevent transfusion-related immunomodulation (TRIM), which is of particular concern in the postoperative period. A large metaanalysis previously demonstrated that patients who receive a blood transfusion are more likely to experience a postoperative infection than patients not transfused. This effect has been found to be dose-dependent and is thought to be mediated by suppression of the patient's immune function. The mechanism of TRIM has yet to be defined, but multiple theories have been proposed. It has been suggested that immunologically active white blood cells or soluble biologic response modifiers released from white blood cells during storage downregulate the recipient's immune function. Alternative theories suggest that soluble mediators that circulate in allogeneic plasma may have an immune modulatory effect. Universal leukoreduction has been found by some studies, but not by others, to mitigate the immunomodulatory effect of allogeneic transfusions.

Washed Red Blood Cells

Red blood cells are washed using isotonic saline solutions by either automated or manual techniques. Automated techniques are more efficient, but there is always some degree of red blood cell loss with each wash cycle. When the washing is performed in an open system, the resulting product must be transfused within 24 hours because of concerns over potential bacterial contamination.

The primary aim of washing is to remove plasma proteins, although some leukocytes and platelets are removed simultaneously. The major indication for washed red blood cells is the prevention of severe allergic transfusion reactions, thought to be mediated by recipient antibodies (most likely IgE) to donor plasma proteins. Washing is recommended when reactions are recurrent and severe, even in the face of steroid and antihistamine administration. In IgA-deficient patients who have preformed antibody to IgA, IgA-containing plasma can cause anaphylaxis. Multiple cell washes may be required to remove the contaminating plasma protein.

Irradiated Red Blood Cells

Red blood cells are irradiated with a minimum dose of 25 Gy. Red cells expire 28 days after irradiation or the original expiration date, whichever is sooner. A method is used to ensure that irradiation has occurred with each batch. The primary aim of irradiation is to prevent the rare, but often fatal risk for transfusion-associated graft-versus-host disease (TA-GVHD) by the abrogation of the proliferative potential of donor T lymphocytes. Graft-versus-host disease can occur after the transfusion of immunologically competent donor lymphocytes, usually to an immunoincompetent recipient. Some patient populations with indications for irradiated products include neonates, patients with hematologic malignancies, stem cell transplant recipients, and patients with congenital immune deficiencies. There is still much debate among experts regarding which additional patient populations may be at risk for TA-GVHD. It has been suggested that a policy of universal blood component irradiation could prevent TA-GVHD in patients with currently unsuspected risks, including advanced age, unrecognized immune deficiencies in the recipient, or unsuspected donor-recipient immune similarities.

Frozen Red Blood Cells

Red blood cells can be frozen (with glycerol, used as a cryoprotective agent) and stored in liquid nitrogen or mechanical freezers. The required concentration of glycerol depends on the rate and the temperature of freezing. The freezing process destroys other blood constituents, except for a small percentage of immunocompetent lymphocytes. Red blood cells are prepared for transfusion by thawing and washing away the glycerol using a series of progressively less hypertonic saline solutions, allowing glycerol to diffuse gradually from the cells to prevent hemolysis. The cells are resuspended in an isotonic saline solution containing glucose. The extensive washing removes approximately 99.9% of the plasma as well as cellular debris.

Red blood cells can be stored in the frozen state for at least 10 years with good viability. After thawing and washing, storage is typically limited to 24 hours because of the open system. Frozen cells have been shown to maintain prefreezing ATP and 2,3-DPG levels. To maintain these factors at high levels, the standard is to freeze within 6 days of collection. When it is necessary to freeze older units, rejuvenation with a solution containing pyruvate, glucose, phosphate, and adenine has provided excellent results. The major indication for frozen red blood cells is the stockpiling of rare donor units for patients who have developed alloantibodies. Some patients with rare phenotypes can make autologous donations that can be frozen for later use. Cells from autologous donors can be frozen if more units are required than can be collected in the 42-day liquid storage period or if surgery

is postponed. Because of the high cost and cumbersome nature of freeze-thaw procedures, other uses of frozen red blood cells are somewhat difficult to justify.

APPROPRIATE TRANSFUSION PRACTICE IN VARIOUS CLINICAL SETTINGS

The response to red blood cell transfusion varies from patient to patient. In the absence of increased red blood cell destruction or sequestration, 1 unit of red blood cells can be expected to increase the hemoglobin level by 1 g/dL or the hematocrit level by approximately 3%. This rise is usually not fully realized until approximately 24 hours after transfusion, when the plasma volume has had time to return to normal. On the basis of a half-life of approximately 57.7 days for donor red blood cells, Mollison and associates calculated that an average-sized adult requires 24 mL of red blood cells per day to maintain a given hematocrit level, assuming no red blood cell production. Patients with red cell aplasia require approximately 2 units of red blood cells every 2 weeks.

Several factors can adversely affect the survival of transfused red blood cells. Hemolysis, caused by either immune red blood cell damage or mechanical trauma, shortens the survival of transfused cells, much as it shortens the survival of the patient's own cells. Hypersplenism can lead to initial sequestration as well as increased destruction of red blood cells. Continued blood loss is another obvious cause of suboptimal response to transfusion. It should also be emphasized that transfusion suppresses erythropoiesis, so that the net result of transfusion may be less than expected if transfusions are administered on a chronic basis.

Chronic Anemia

As a rule, signs and symptoms attributable to anemia are unlikely to develop at a hemoglobin level of greater than 7 or 8 g/dL. When the anemia is of gradual onset, the body's compensatory mechanisms for maintaining oxygen delivery to the tissues come into play. Both cardiac output and intracellular 2,3-DPG increase, and thus oxygen unloads at a lower oxygen saturation of hemoglobin. When chronic anemia is due to red blood cell destruction, the healthy bone marrow responds by increasing production up to sixfold.

Red blood cell transfusion is always symptomatic and supportive rather than definitive therapy for anemia. Transfusion should be used only when there is no definitive treatment for the underlying cause or when the severity of the anemia and the clinical manifestations in the patient make it impossible to wait for the effects of the treatment to be realized.

Generalizations about whether or when to transfuse red blood cells, and how many, are difficult to make and are usually inappropriate. The clinical impact of anemia varies, depending on its pathogenesis, rate of onset, the presence or absence of accompanying hypovolemia, and most important, the individual patient. The hemoglobin level at which a given individual manifests the signs and symptoms of anemia relates, in part, to underlying health status, cardiorespiratory reserve, and activity level.

Perioperative Period

Many generalizations have been made about the appropriate transfusion management of acute blood loss, often with little hard data to support the arguments. One rule of thumb is that blood loss of 10% or less of total blood volume requires no replacement therapy at all; loss of up to 20% can be replaced exclusively with crystalloid solutions; and loss of greater than 25% generally requires red blood cell transfusion to restore oxygen-carrying capacity, along with crystalloid and sometimes colloid solutions to restore intravascular volume to maintain perfusion. For years, the figure of 10 g/dL of hemoglobin had been used as the gold standard for the red blood cell transfusion trigger during the perioperative period, but 7 g/dL is now more commonly used. Each case must be evaluated individually on the basis of clinical signs and symptoms, rather than on the basis of laboratory values. If the cardiovascular system is healthy and the degree of hypoperfusion is not significant, good tissue oxygenation can be maintained at much lower hemoglobin levels. A National Institutes of Health consensus conference suggested that many surgical patients do not need transfusion unless the hemoglobin level falls to less than 7 g/dL. Given that red blood cell transfusion should be tailored to individual needs, the question arises as to whether there is any readily available, objective measurement that can be used to determine how low the hemoglobin level can safely be allowed to fall before red blood cell transfusion is initiated.

Global hemodynamic parameters do not always correlate with microvascular perfusion. Assessment of tissue oxygenation at the microvascular level would help evaluate the effectiveness of a red cell transfusion, evaluate the effect of red cell storage on end-organ perfusion, and provide data about when to transfuse. Several general methods are available to evaluate the microcirculation and include direct assessment using image techniques and indirect methods of assessment, such as measures of microvascular oxygen availability and function. Direct assessment can be performed using laser Doppler flowmetry, imaging of the microcirculation, intravital microscopy, orthogonal polarization spectral imaging, and sidestream dark-field imaging. Assessments of oxygen availability include oxygen electrodes, reflectance spectrophotometry, and near-infrared spectroscopy. The techniques described are currently considered research tools and are not available in routine clinical practice. Many have yet to prove reliable and reproducible in the clinical setting. Further, some are useful only in specific organ systems and do not reflect the global oxygenation of the patient. To be useful at the bedside, a technique must be technically simple, rapid, and noninvasive without large interoperator variation. Such a device has yet to become available.

The Society of Thoracic Surgeons and the Society of Cardiovascular Anesthesiologists published clinical practice guidelines that identified six variables that increased a patient's risk for postoperative blood transfusion: advanced age, low preoperative red blood cell volume, preoperative antiplatelet or antithrombotic drugs, reoperative or complex procedures, emergency operations, and noncardiac patient comorbidities. The report recommended developing institution-specific protocols to screen for high-risk patients and apply blood conservation interventions, such as erythropoietin or antifibrinolytic administration, intraoperative blood salvage or normovolemic hemodilution, and institution-specific blood transfusion algorithms supplemented with point-of-care testing.

Randomized clinical trials have evaluated the effects of different transfusion thresholds in the surgery setting; however, the thresholds used in the studies differ widely. Many of the studies found no difference in outcome. Most studies were not powered to adequately evaluate clinically important outcomes. Few included more than 100 patients. The Transfusion Requirements in Critical Care (TRICC) trial included 838 ICU patients who were randomized to a restrictive transfusion strategy (transfused at Hb 7 g/dL) or liberal strategy (transfused at 10 g/dL). The 30-day mortality was slightly lower in the restrictive group (18.7% versus 23.3%), but not significantly lower. The FOCUS trial (Functional Outcomes in Cardiovascular Patients Undergoing Surgical Hip Fracture Repair), a 2600-patient, multicenter randomized trial designed to determine whether patients with cardiovascular disease or cardiovascular risk factors undergoing surgical repair of the hip benefit from a lower or higher transfusion trigger, has recently completed. The results suggest that patients do not benefit from liberal transfusion therapy.

The possibility of immunomodulation by allogeneic transfusions in humans was first suggested more than 30 years ago when improved renal allograft survival was reported in pretransplant transfusion recipients. A potential link between allogeneic transfusion and an increased rate of cancer recurrence and postoperative infection was first raised in the 1980s, and numerous retrospective and prospective observational studies supporting these contentions have been reported in the literature since that time. These studies, as well as reports from

investigations with opposing data, have been analyzed in numerous reviews on the topic. Studies in experimental animals have also yielded contradictory results. Research using animal models and human subjects on the specific immunomodulatory effects of transfusion has consistently pointed to depression of cell-mediated immunity, although the specific defects seen have varied. The mediators of these immunomodulatory effects appear to be leukocytes present in cellular blood components, including whole blood and red blood cells. Several well-designed, prospective, randomized controlled trials comparing transfusion of leukoreduced blood components or autologous blood with transfusion of unmodified allogeneic blood components have reported inconclusive results. Although controversy exists about whether red cell transfusions produce immunomodulatory effects, such as cancer recurrence or perioperative surgical infections, the use of leukoreduced red cell components has been advocated as a means to mitigate the effects of transfused white cells.

Red Blood Cell Transfusion in Neonates

In neonates it is convenient to consider periodic, small-volume transfusion separately from massive transfusion situations. The trigger for transfusion and the optimal type of component are very different in the two settings. The potential adverse effects may be quite distinct.

Low-volume red blood cell transfusion is rarely indicated in full-term infants unless acute blood loss has occurred at birth or an intrauterine situation has led to prenatal anemia. In contrast, premature infants are frequent recipients of transfusions. In the intensive care setting, the premature infant is subjected to frequent blood sampling, and iatrogenic anemia may necessitate transfusion. Anemia of prematurity is also a well-recognized entity; premature infants have a slightly lower Hb value at birth. In addition, the postnatal decline in Hb occurs earlier and is more pronounced in premature infants. The mechanism for anemia of prematurity appears to involve a relatively lower output of erythropoietin in response to a given degree of anemia. This phenomenon is attributed in part to the fact that the liver, rather than the kidney, is the major site of erythropoietin production in these infants. Although some practitioners have considered this degree of anemia to be physiologic, the benign nature of this condition remains controversial.

Another debate among neonatologists concerns the triggers for red blood cell transfusion, as in what clinical signs and symptoms are valid reflections of poor tissue oxygenation. Congestive heart failure and severe pulmonary disease are generally accepted indications for transfusion, but recurrent apnea, tachypnea, tachycardia, and failure to thrive are also used as transfusion triggers. In recent times, the rate of transfusion and the donor exposure rate of premature infants have consistently declined. These changes, however, reflect improvements in patient care (e.g., microtesting methods resulting in less iatrogenic blood loss; the use of surfactant resulting in decreases in respiratory distress) and the use of a single unit to supply one infant over a longer period rather than being attributable to changes in the transfusion trigger. The prolonged use of single units has become possible with the advent of the sterile docking technology, which preserves the full shelf life of the unit of red blood cells, as well as with the accumulating solid evidence that fresh blood is not necessary for low-volume transfusions in neonates, because supernatant potassium and decreased pH are not of concern in this setting. Two recent studies have provided additional information about the relative risks and benefits of using restrictive rather than more liberal criteria for very-low-birthweight infants. One study showed that a liberal transfusion practice resulted in more infants receiving transfusion but conferred little evidence of benefit. The other study showed a lower risk for apnea and major brain injury for the liberal transfusion arm of the study. Therefore the safest transfusion trigger in the preterm infant still remains unclear and further studies are indicated. Most institutions assess the clinical situation and consider the postnatal age and whether a neonate has oxygen requirements when determining the need for a red blood cell transfusion.

The dose of an RBC transfusion in a neonate can vary by institution between 5 to 20 mL/kg. Few studies have assessed the optimal dose in this patient population, and further studies are needed. Paul and colleagues compared 10 and 20 mL/kg and found that the larger volume did not cause impaired pulmonary function. Wong and colleagues demonstrated that extra transfusion episodes could be avoided with 20 mL/kg versus 15 mL/kg, without any additional risk to the patient. Many transfusion services now routinely use red blood cells stored in additive solutions for low volume red blood cell transfusion and thus prefer a dose of 20 mL/kg to account for the lower hematocrit of an additive unit.

Finally, several trials of erythropoietin therapy in premature infants have been undertaken. The administration of relatively high-dose erythropoietin has been shown to raise hemoglobin levels and reticulocyte counts in healthy premature infants, but the effect in sicker neonates is unclear. Although transfusion exposure was decreased, the significance of this observation is diminished, given the promise of new strategies for limiting transfusions and donor exposure. The high cost and the increased risk for retinopathy associated with erythropoietin treatment does not justify its use in this patient population.

In the case of massive transfusion, the situation differs. There have been marked increases in massive transfusion in recent years in full-term as well as premature infants. Hemolytic disease of the newborn remains a prominent indication for exchange transfusion; however, the recent use of intravenous immune globulin to decrease red cell antibody levels in newborns has decreased the necessity of this procedure. The two triggers for exchange are (a) rapidly rising levels of unconjugated bilirubin that may lead to kernicterus and permanent central nervous system damage and (b) congestive heart failure secondary to severe anemia. Exchange transfusion is especially beneficial in cases of hemolytic disease of the newborn because it clears the bilirubin and the offending antibody from the circulation and removes antibody-coated red blood cells before lysis, while providing a source of red blood cells lacking the offending antigen. A two-blood-volume exchange is commonly performed by using a fresh unit of blood concentrated to a final hematocrit level of approximately 50%. In cases of hyperbilirubinemia resulting from other causes (e.g., that associated with liver immaturity in premature infants), phototherapy is the treatment of choice because its effects are usually more sustained, and exchange transfusion is used only for cases of marked elevations. Extracorporeal membrane oxygenation and open-heart surgery are two other situations in which the neonate may be exposed to large volumes of allogeneic red blood cells. The extracorporeal membrane oxygenation circuit requires a prime with red blood cells, as do many of the types of extracorporeal circuits used for cardiopulmonary bypass.

Although accumulating evidence supports the safety of using red blood cell units of any age and with any preservative solution for low-volume transfusions in neonates, the same transfusion policies may not apply to massive transfusion. Newborn physiology is unique in several ways that may have implications for massive transfusion therapy. The newborn does not handle metabolites in a mature fashion. Renal immaturity may lead to problems in clearing potassium or acid from stored red blood cells, and the immature liver may not catabolize citrate efficiently. These problems are accentuated and protracted in the premature infant. To address the concern about potassium load, fresh (<5 days old) or washed red blood cells are often used, although the necessity of this practice is actively debated. Fresh blood may also be preferred because of its higher 2,3-DPG levels and better red blood cell integrity. The citrate problem is probably best handled by using slow infusion rates, because the use of bicarbonate or calcium replacement to counteract the acid load or calcium-chelating effects of citrate is controversial. Finally, the use of red blood cells stored in the newer preservative solutions (CPDA-1, Adsol, Nutricel, Optisol) is avoided by some authorities because of the risk for renal damage and renal stones due to adenine metabolites. If CPD red blood cells are not available, the additive solution can be removed and the cells washed. Red blood cells preserved in additive solutions also have a lower hematocrit, which must be taken into account in making calculations for exchange transfusion.

The humoral and cellular immune systems of the neonate are immature, especially in the premature infant. There is a small but real risk for transfusion-induced graft-versus-host disease in premature infants receiving red blood cell transfusions and in the fetus undergoing intrauterine transfusion. Irradiation of red blood cells should be performed in both settings. Another risk of transfusion in low-birth-weight (<1500 g) premature infants is the development of clinical cytomegalovirus (CMV) infection in infants of cytomegalovirus-seronegative mothers. CMV-safe blood, either CMV seronegative or leukoreduced, should be provided to these infants.

Novel ideas to decrease donor exposure in neonates include delayed cord clamping in premature infants and autologous cord blood transfusion. One review of 10 delayed cord clamping studies demonstrated lower transfusion requirements in the delayed versus early clamped group. However, a randomized controlled trial by Strauss found no difference in transfusion needs between delayed versus early clamped groups. A few studies have looked at autologous cord blood transfusions in neonates. One study found that the amount of blood harvested was insufficient to cover all transfusions in low-birth-weight infants. In addition, studies have demonstrated that blood processing problems, bacterial contamination and costs are all barriers to the routine collection and autotransfusion of cord blood.

RED BLOOD CELL PRESERVATION AND STORAGE

The first key to the storage of blood is a stable, minimally toxic anticoagulant with preservative properties. During the early 1900s, it was recognized that citrate met these criteria. Citrate is slightly more toxic than heparin, especially when given rapidly and in large amounts, but citrate has preservative action that heparin lacks. Citrate has the added advantage of not causing systemic anticoagulation in the recipient.

The other factor essential for long-term storage is a mechanism to maintain cell viability and function. Fresh transfused red blood cells have a good survival rate in the recipient's circulation, with a destruction rate approximately equal to that of the recipient's own cells: 1% per day.

Discoveries during the past 2 decades have raised clinical concern regarding the efficacy and risks of RBC transfusion. Changes within the RBC and its supernatant during RBC storage have been associated with reduced tissue oxygenation and other adverse effects in patients receiving red blood cell components stored for extended periods. The biochemical, structural, and functional changes are collectively termed the *red cell storage lesion*. The alterations found with the storage lesion, along with the clinical implications, will be discussed in this section.

Biochemical Changes Associated With Red Blood Cell Storage

Adenosine Triphosphate Levels

Adenosine triphosphate (ATP) levels appear to be a major determinant of red blood cell viability. The drop in cellular ATP levels during storage has been correlated with increased cell rigidity and with loss of membrane lipid, leading to decreased red blood cell life span. For this reason, most efforts to extend red blood cell storage have focused on ways to maintain intracellular ATP levels. First, dextrose was introduced into the citrate solution (citrate-phosphate-dextrose [CPD]: 21 days), and then adenine was added (CPDA-1: 35 days). Three additive solutions containing additional dextrose and adenine (Nutricel, or AS-3) or dextrose and adenine plus mannitol (Adsol, or AS-1) and (Optisol, or AS-5) allow extension of the maximum storage time to 42 days (Table 112-2). The majority of today's red blood cell supply is stored in an additive solution.

Table 112-2 Biochemical Changes in Stored Red Blood Cells

	CPDA-1	*CPDA-1*	*Adsol*
Variable	**Fresh**	**35 Days**	**35 Days**
In vivo survival (at 24 hours) (%)	100	<71.0	<88.0
pH	<7.5	<6.7	<6.7
ATP (% initial)	100	<45.0	<76.0
2,3-DPG (% initial)	100	<10.0	<10.0
Plasma K^+ (mEq/L)	5.1	<78.5	<49.0

Data from Zuck TF, Bensinger TA, Peck CC, et al: The in vivo survival of red cells stored in modified CPD with adenine: report of a multi-institutional cooperative effort. *Transfusion* 17:34, 1977; and Moore GL, Peck CC, Sohmer RR, et al: Some properties of blood stored in anticoagulant CPDA-1 solution: a brief summary. *Transfusion* 21:135, 1981.

2,3-Diphosphoglycerate Levels

Stored red blood cells must also maintain their capacity to deliver oxygen. It was not until 1967 that the central role of 2,3-diphosphoglycerate (2,3-DPG) in releasing oxygen from oxyhemoglobin was recognized. Attention was then focused on ways to maintain high levels of 2,3-DPG in stored blood cells. The first anticoagulant introduced on a large scale, acid citrate-dextrose, was ineffective because of its low initial pH; however, the subsequently developed CPD, with its higher initial pH and slower fall in pH, was superior. CPDA-1 and additive solutions have not further improved 2,3-DPG maintenance. Although 2,3-DPG depletion of stored red blood cells is known to decrease oxygen delivery, the clinical significance of this finding is unclear. 2,3-DPG levels in stored blood cells are rapidly regenerated in vivo, rising to greater than 50% of normal within several hours and to normal within 24 hours. Although a patient with normal cardiac status should be able to compensate by increasing cardiac output to maintain normal oxygen delivery until 2,3-DPG levels are regenerated, an improvement in 2,3-DPG preservation in stored red blood cells is still desirable.

Citrate

Infusion of large volumes of blood with citrate anticoagulant over a short period may cause plasma citrate levels to reach the toxic range. The primary concern is the cardiovascular effects of hypocalcemia caused by chelation of calcium by citrate. The risk for citrate toxicity is exacerbated by liver dysfunction or liver immaturity. Despite these theoretical considerations, there is little documented evidence of clinical citrate toxicity, and the problem can usually be prevented by slower infusion. If large amounts of blood have to be infused over a very short period, administration of calcium gluconate can be considered, but whether the benefits justify the risk is controversial.

Potassium

Another issue with prolonged storage is the excess potassium in the red blood cell supernatant that could potentially cause cardiac arrhythmias. At a storage temperature of 4° C, the red blood cell sodium-potassium pump is essentially nonfunctional, and intra- and extracellular levels gradually equilibrate. In addition, hemolysis results in increased potassium in the supernatant. However, because the total volume of plasma in red blood cell concentrates is low (approximately 70 mL), the total potassium burden is only approximately 5.5 mEq at product expiration. Practically speaking, the potassium load is rarely a clinical problem except in the setting of preexisting hyperkalemia and renal failure. In this situation, fresher units of red blood cells or washed red blood cells can be used.

DEHP

Since their introduction in the 1960s, plastic blood bags used for storing red blood cells have been made from polyvinylchloride containing the lipophilic plasticizer di(2-ethylhexyl)phthalate (DEHP), which confers pliability. The safety of DEHP has been questioned for years owing to its tendency to leach from the bag and to be present at levels of 50 to 70 mg/L in stored red blood cells. The storage of RBCs in bags made of polyvinyl chloride plasticized with DEHP has caused more concern recently because of the reported association between DEHP exposure and impaired development of the male genital tract. One of the benefits of the use of DEHP for red blood cell storage is the prevention of hemolysis. DEHP leaches out from the plastic bag and intercalates and stabilizes the red cell membrane. Shorter storage lessens the load of DEHP delivered to the recipient. Although there are potential replacement plasticizers, DEHP is most commonly used since the exposure to DEHP through transfusion is generally felt to be less than through other environmental exposures.

Storage Length of Red Blood Cells

Current Status

The current expiration time of a red blood cell unit stored in an additive solution is 42 days. The allowable storage time is regulated by the FDA and requires (1) the recovery of at least 75% of red cells transfused 24 hours after infusion and (2) less than 1% hemolysis, both at the end of the storage limit. There is no criterion based on the clinical ability of transfused red cells to oxygenate tissue. The 2009 National Blood Collection and Utilization Survey reported that the mean age of red blood cell units at transfusion was 18.2 days.

Many variables affect the age of a specific red blood cell unit at transfusion. The blood group of the unit will impact the length of storage. Group O units tend to be issued quickly because of their universal compatibility; as a result, Group O units are often issued with a shorter age. Group B and AB tend to be stored the longest. Transfusion service type will also affect the overall age of red blood cell units at the time of transfusion. Busy tertiary care hospitals tend to transfuse some of the oldest units since they may receive units returned from smaller community centers that did not expect to use them before their outdate. Hospitals that have blood refrigerators outside the blood bank tend to age units in the refrigerators because it is cumbersome to rotate the units out frequently. Hospitals with high crossmatched-to-transfused ratios also tend to have older units on their shelves.

Red Cell Storage Lesion

The red blood cell storage lesion includes all the changes that occur to blood components during blood bank storage. The lesion includes biochemical and structural changes to the red cell, as well as changes that occur in the storage supernatant. The structural changes include red cell membrane loss that leads to the reversible evolution of the shape of the red cell from a biconcave disc to a spheroechinocyte. After this stage, further red cell membrane loss becomes irreversible and microvesicles are produced. Red cell vesicles are quickly cleared by macrophages as a result of exposed negatively charged lipids. The infusion of a large amount of red cell vesicles during a red blood cell transfusion may overwhelm the reticuloendothelial system and cause a proinflammatory and prothrombotic response. The shape changes are also associated with a rheologic effect, including increased viscosity and reduced flow within the capillaries, leading to decreased tissue perfusion. Many of the biochemical and structural changes, aside from vesiculation, are reversible when the red blood cells enter human circulation where pH, ATP levels, and 2,3 DPG levels are normal.

Older red cells become more susceptible to oxidative damage, although this change generally occurs at a lower rate during in vitro conditions than in vivo because of the lower storage temperature. However, during a transfusion the human circulation is confronted by a bolus of equally damaged red blood cells that may overwhelm the reticuloendothelial system. Irradiated cells are exposed to additional oxidative stress that can damage red cell protein and lipid. White blood cells in the component also break down during storage and release proteases and lipases. Lysophospholipids and glycosidases are produced. Glycosidases may remove sialic acid and other sugars from the red cell membrane and can cause increased binding of stored red cells to endothelial cells and potentially contribute to endothelial inflammation. Increased lysophospholipids, such as platelet activating factor, have been found in units that have caused transfusion-related acute lung injury (TRALI).

Clinical Relevance of the Red Cell Storage Lesion

Retrospective or prospective observational studies in many diverse patient populations have suggested numerous adverse events that may be associated with prolonged red blood cell storage, including increased risk for mortality, postoperative infection, multiorgan failure, deep venous thrombosis, or increased length of stay in the ICU or hospital. The observational studies on this topic have a number of significant limitations. First, larger volumes of RBC transfusion predict worse outcomes. Patients who are transfused larger volumes are statistically more likely to receive older RBCs. Second, confounding factors may not be recognized and discounted in nonrandomized studies. Third, individual methodologies in the presently available studies have varied markedly. Some studies have looked at the effect of mean storage age of all units transfused on outcome, and some have broken storage time into categorical groups (i.e., is storage less than 14 days safer than storage beyond 14 days). In addition, studies have not used a single definition for "older" units; some have defined older units as greater than 14 days, greater than 21 days, or greater than 28 days. The definitions of age have not been based on either clinical or microcirculatory relevance or related to the feasibility and practicality of blood collection. Most studies have been designed for convenience and feasibility; a study of red cell storage age with a definition of an older red blood cell unit as greater than 14 days of storage is achievable given current hospital inventories. Although 14 days is close to the average age of RBCs stored in a blood bank, from a blood collection and inventory management perspective, an expiration time of 14 days would be disastrous for both hospitals and blood collection facilities. Authorities have argued that studies should be designed to measure storage age differences between lengths of storage that would be achievable given current inventory levels and those that would be feasible during times of difficulties in donor recruiting.

Published studies have focused on three patient groups that consume large numbers of RBC components: cardiac surgery, trauma, and critical care patients. A publication on the effect of red blood cell storage age on hematopoietic transplant recipients has also been recently published. The cardiac surgery studies have confirmed the previous finding that large numbers of red blood cell transfusions are associated with adverse outcomes, largely reflecting the patient's underlying condition. If the number of units transfused is controlled for, the effect of the RBC storage lesion is difficult to discern in cardiac studies. The majority of studies in cardiac and trauma patients addressing red blood cell storage duration have reported negative outcomes with longer storage, but none has been both large and randomized, and even multivariate analysis cannot separate all potential confounding effects. Unlike in cardiac surgery and trauma, there have been three prospective, randomized trials addressing the storage lesions in ICU patients. Adverse effects with longer storage were not demonstrated in these studies.

Although the randomized prospective trial seems to be the only option to determine the clinical consequences of the red blood cell storage lesion, conducting a well-designed trial is not an easy task. Limited blood bank inventories to supply the longer and shorter

storage duration arms, difficulty in consenting patients, and the difficulty in selecting outcome measures to study have plagued the previously attempted studies.

Three large, multicenter, randomized, double-blinded trials are underway in North America investigating three different patient groups. The Age of Blood Evaluation (ABLE) study will investigate the effect of leukoreduced red blood cells stored 7 days or less versus leukoreduced standard-issue red blood cells on 90-day all-cause mortality. Investigators will attempt to enroll 2510 adult subjects receiving their first red blood cell unit in an intensive care unit. The study is powered to detect a 5% absolute risk reduction. A second study, the Age of Red Blood Cells in Premature Infants (ARIPI), is a double-blinded study that will evaluate the effectiveness of RBCs stored no longer than 7 days versus standard-issue red blood cells in 450 neonates requiring transfusions. The primary outcome for this study will be a composite measure of major neonatal morbidities. The study is powered to detect a 15% absolute risk reduction. Finally, the Red Cell Storage Duration Study (RECESS) will evaluate 1434 pediatric and adult subjects undergoing complex cardiac surgical procedures who are likely to require red blood cell transfusion. Subjects will be randomized to receive red blood cell units stored either for 10 or fewer days or for 21 or more days. Randomization will occur only if the blood bank has enough units of red blood cells of both storage times to meet the crossmatch request. The primary outcome is the change in the multiple organ dysfunction score (MODS) since a mortality outcome would have required too many patients.

The published studies evaluating whether adverse clinical consequences are associated with prolonged red blood cell storage have yet to satisfactorily answer this important question in any patient population. The anticipated publication of the three randomized, controlled studies in the coming years may provide an answer to this question in a specific patient population; until these results are available, clinicians should continue to use red cells for their permissible storage period. It is important to remember that if one of these studies does find worse outcomes with longer storage age duration, many questions and obstacles will remain before this issue can be resolved. If proven, the adverse clinical effects will most likely apply not only to the patient population studied, but to all patients. Further, the current red blood cell inventory almost always meets hospital needs with a 42-day RBC expiration period but is not currently equipped to meet the needs of a less than 7-day inventory, or even a less than 21-day inventory. Finally, although it is logical to expect that there is a limit to red blood cell storage, beyond which the risks of transfusion outweigh the benefits of transfusion, none of the randomized studies just described is designed to determine this limit.

ALTERNATIVES TO ALLOGENEIC RED CELL TRANSFUSIONS

There are many alternatives to standard allogeneic red cell transfusions for a patient requiring elective surgery (Table 112-3). Potential alternatives include banking autologous units before the surgery, acute normovolemic hemodilution, pharmacologic therapies (i.e., erythropoietin or fibrinolysis inhibitors), perioperative salvage, virally inactivated donor red cells, or blood substitutes. All current options have their own unique benefits and drawbacks, and some of these alternatives are not yet available. In cases where an emergency transfusion is needed, the first three options would not be possible, because they all require significant planning. Only virally inactivated components and red cell substitutes (both of which are still works in progress) would be available for unanticipated transfusion needs.

Table 112-3 Alternatives to Standard Allogeneic Transfusions

Autologous Blood Transfusion

Advantages of Autologous Blood Transfusion

The substitution of autologous blood components for those collected from other (allogeneic) donors eliminates transfusion-transmitted diseases such as hepatitis and acquired immunodeficiency syndrome. Immunologic complications related to the transfusion of foreign cells, including hemolysis and febrile reactions to white blood cells, are also prevented. Other advantages, though possible, are less clearly established. For example, erythropoiesis may be sufficiently stimulated in the repeatedly bled autologous donor to hasten recovery from postoperative anemia. Intraoperatively salvaged red blood cells are spared the acquired membrane defects (storage lesion) and 2,3-diphosphoglycerate deficiencies of refrigerated red blood cells.

An important drawback to these techniques is their increased expense, in contrast to the simpler allogeneic transfusions they replace. In addition, the availability of autologous components may result in their use in situations where transfusion might not have otherwise been considered. Patients with suboptimal compensatory erythropoiesis and donation-induced anemia at the time of surgery are also more likely to be given transfusions. Based on the current level of viral safety in blood components in the developed world, the use of autologous blood has dropped significantly from times when viral testing was not available or reliable.

Some patients and their families ask for directed blood donations, hoping to select blood donors that are known to them and presumably have less risk. This practice has not been shown to have any medical benefit, may cause reduced or delayed blood availability, and should not be considered a worthwhile transfusion alternative.

Preoperative Autologous Blood Collection

The typical volunteer allogeneic blood donor is allowed to give 1 unit of blood no more than once every 8 weeks, to prevent iron deficiency. However, provided that bone marrow erythropoiesis can be stimulated and satisfactory iron supplies maintained, blood can be collected as frequently as once a week from an autologous donor. Although the shelf life of refrigerated red blood cells is limited to 42 days, frozen storage for up to 10 years is possible at less than −65° C, using glycerol as a cryopreservative.

From a cardiovascular standpoint, phlebotomy is well tolerated by a variety of seemingly high-risk donors, including older adults, children, pregnant women, and patients with coronary artery disease. By contrast, anemia frequently develops during the donation interval and limits the number of autologous units that can be collected. In addition to marginal iron stores, erythropoietin levels often do not increase during the donation interval, probably because the hematocrit level of most donors is not allowed to fall to less than 30%. This situation may be improved by the administration of the recombinant growth hormone erythropoietin to autologous donors. The use of preoperatively donated autologous blood has also been reported for a variety of surgical procedures, including radical prostatectomy; hysterectomies and other gynecologic procedures; colorectal, biliary, and gastric surgery; orthopedic surgery; and neurosurgery.

Autologous blood has been safely collected from women during pregnancy for use during childbirth. Nevertheless, the transfusion rate at delivery is quite low (<2.5% in many institutions), and most autologous donations are unused. Long-term (frozen) storage of autologous red blood cells in the absence of a planned transfusion episode is largely ineffective and expensive.

Intraoperative Blood Salvage

Cell salvage occurs in three phases: collection, washing, and reinfusion. RBCs are collected from the operative field using a dedicated double-lumen suction device. One lumen suctions blood from the operative field, and the other lumen adds heparinized saline to the salvaged blood. The anticoagulated blood then passes through a filter and is collected in a reservoir. If less than 1 L of blood is collected, further processing is foregone and the collected blood is discarded.

In most circumstances the contents in the bag can be washed to remove free hemoglobin, surgical irrigant solutions, and other debris. Instruments are available that include both a reservoir for collecting salvaged blood and a centrifugal washer. Large aliquots (>500 mL) can be fully washed in as little as 3 minutes. As a result of this speed, autologous blood salvage has become practical in situations in which blood loss may be extremely rapid, such as trauma or liver transplantation.

The hematocrit level of unwashed blood is typically low because of dilution from irrigating surgical fluids and some degree of mechanical hemolysis. Free hemoglobin levels are sometimes greater than 1000 mg% in unwashed blood, and hemoglobinemia and hemoglobinuria may occur after the transfusion, although renal sequelae are surprisingly low. Despite this evidence of red blood cell injury, the survival rate of ^{51}Cr-labeled salvaged cells is normal in most patients studied.

Many potential complications are associated with cell salvage, such as nonimmune hemolysis, air embolus, febrile nonhemolytic transfusion reactions, mistransfusion, coagulopathy, and contamination with drugs. Transfusion of salvaged blood has resulted in coagulation abnormalities, including hypofibrinogenemia, prolonged prothrombin time and partial thromboplastin time, elevated fibrin degradation products, and thrombocytopenia. These coagulation abnormalities most likely reflect the characteristics of the salvaged blood itself, which, after exposure to serosal surfaces, becomes deficient in coagulation factors and platelets and, in the case of unwashed blood, has high levels of fibrin degradation products (Table 112-4).

Fat, fibrin, bone fragments, and microaggregates often contaminate salvaged autologous blood. However, infusion of unwashed blood has not been proved harmful in either animals or humans, possibly because routine blood filters remove most particulate material. Other contaminants, such as heparin, topical antibiotics, hemostatic agents, and biologic substances such as tissue enzymes, can be at least partially removed by washing. Complete removal of bacteria is also not possible, even when the salvaged blood is washed with antibiotics. Thus collection of blood from a contaminated site (e.g., with intestinal contents) is usually considered to be contraindicated; in fact, manufacturers contraindicate the use of cell salvage in cases in which there is potential contamination of salvaged blood with enteric contents. However, in recent years this viewpoint has been reconsidered, because studies have found that autotransfusion of microbiologically contaminated salvaged blood have demonstrated no adverse outcomes or increase in postoperative infectious complications. Tumor cells have been found in blood salvaged during cancer operations and many practitioners consider cancer another contraindication; others believe that filtration would remove salvaged tumor cells.

Approximately one-half the blood lost during surgery can be salvaged. The rest is usually irretrievably absorbed in drapes and sponges or damaged during collection. The use of salvaged autologous blood has been associated with a 50% reduction in allogeneic blood use in orthopedic procedures such as spinal surgery and hip replacement and is also effective in vascular surgical procedures such as aortic reconstruction. Autologous salvage has been a useful adjunct in the treatment of some Jehovah's Witnesses, whose literal acceptance of the Bible includes abstention from routine allogeneic blood transfusions.

Both the canister systems and red blood cell processors used to collect intraoperative autologous blood can also be employed to collect postoperative blood drainage, such as that from the mediastinum after open heart surgery, from the knee or hip after orthopedic procedures, or from the peritoneal cavity after hepatic injury. Because blood salvaged from a serosal cavity has little residual fibrinogen and platelets, clotting is not a problem, and the addition of anticoagulants is usually unnecessary. Shed mediastinal blood after open-heart surgery contains high levels of cardiac muscle enzymes, especially creatine kinase, as well as lactate dehydrogenase from hemolyzed red blood cells. Therefore reinfusion of shed blood results in elevated levels of both enzymes, which can confound the diagnosis of myocardial infarction in the postoperative period. Reinfusion of shed mediastinal blood has been shown to reduce the need for allogeneic transfusions.

Hemodilution

The collection of autologous blood during surgery for later reinfusion at the end of the procedure was first suggested in open-heart operations, in which it was hoped that a supply of platelets undamaged by exposure to the membrane oxygenator might reduce the incidence of coagulopathies. Hemodilution itself reduces red blood cell loss: a patient with a hematocrit level of 45% and 2 L blood loss during surgery loses roughly 900 mL of red blood cells, but one with a hematocrit level of 20% from hemodilution loses only 400 mL of red blood cells. Hemodilution is less expensive to accomplish than preoperative autologous blood donation and may be the only option available when surgery is performed in nonelective settings. Proponents claim that the induced anemia may even be beneficial to the patient, in that oxygen delivery at a hematocrit level of 30% is enhanced by an increased cardiac output resulting from the decreased blood viscosity.

Reductions in allogeneic blood needs have been reported after marked intraoperative hemodilution (after the hematocrit is lowered by 50%). More modest hemodilution (e.g., removal of 2 U of blood at the beginning of surgery) is also beneficial, according to some

Table 112-4 Autologous Blood Salvage Systems* Characteristics of Collected Blood

System	Hardware	Software	Hematocrit	Free Hemoglobin	Platelet Count	Coagulation Factors	Fibrin Degradation Products
Collection without washing	Rigid plastic container	Plastic bag	Low (25%)	Very high (200 mg%)	Low (100,000/mm^3)	Low (35%-75%)	High (300 mg%)
Collection followed by washing	Integral or separate blood cell processor	Disposable plastic bowl and tubing	High (60%)	Low (<50 mg%)	Very low (10,000/mm^3)	Absent (0%)	Absent (0%)

Data from Noon GP: Intraoperative autotransfusion. *Surgery* 84:719, 1978; and Silva R, Moore EE, Bar-Or D, et al: The risk: benefit ratio of autotransfusion-comparison to banked blood in a canine model. *J Trauma* 24:557, 1984.
*Typical results of laboratory tests are shown. Transfusion of large volumes of salvaged blood results in similar alterations in these tests in the recipient.

investigators but the amount of red cells saved is small. Furthermore, one group has provided evidence that hemodilution may jeopardize patients at risk for ischemic myocardial injury. More research is needed to establish the safety, efficacy, and ideal protocols for this form of blood conservation. Future availability of blood substitutes could facilitate augmented hemodilution for some patients who are expected to have large volumes of blood loss or who refuse blood transfusions.

BLOOD SUBSTITUTES

The search for blood substitutes began when our early scientific ancestors tested alternatives to human blood, including animal blood, milk, and wine. Modern research into the use of animal blood includes the work by Amberson and colleagues, who reported the successful use of a bovine hemosylate for exchange transfusions in cats and dogs. Further work revealed that human and bovine hemosylates caused renal dysfunction in human recipients. The suspected cause of this nephrotoxicity was the stromal lipid component of the RBC membrane. The logical next step in the search for the ideal substitute was the development of stroma-free hemoglobin (hemoglobin tetramer). Unfortunately, in 1978, Savitsky and colleagues demonstrated renal dysfunction, hypertension, and abdominal pain using stroma-free hemoglobin in healthy volunteers. It was hypothesized that these adverse events were due to the instability of the hemoglobin tetramer. Since then, efforts have been made to produce stabilized products with desirable oxygen off-loading characteristics and extended intravascular retention times.

Today, the U.S. blood supply is safe and has sufficient capacity to meet most patient needs. There is room for considerable improvement, however, in supply levels and risk reduction. The gap continues to narrow between a shrinking donor pool (owing to willingness and/or ability) and increasing transfusion requirements of an aging population. The threat of new and emerging infections results in the vulnerability of human-derived oxygen carriers. The continuous battle against emerging infectious disease underscores the risk for a tainted blood supply and depletion of transfusion resources. Theoretically, the ideal red cell substitute would solve both of these issues (Table 112-5). Many attempts have been made to develop red cell substitutes in the past, but no product has been able to fulfill all of the aforementioned criteria or meet the Food and Drug Administration's requirements of purity, potency, and safety. No licensed red cell substitute is available.

TYPES OF RED CELL SUBSTITUTES

It is important to differentiate between "blood substitutes" and red cell substitutes. Red cell substitutes are oxygen carriers and do not replace all components and functions of blood, for example, coagulation factors and white blood cells. Two main categories of oxygen carriers show promise as red blood cell substitutes: perfluorocarbons (PFCs) and hemoglobin-based oxygen carriers (HBOCs).

Table 112-5 The Ideal Red Cell Substitute

Delivers oxygen (and maybe enhances delivery)
Does not transmit disease
Does not have immunosuppressive effects
Available in abundant supply
Universally compatible (no need to type and crossmatch)
Prolonged shelf life and stable at a range of temperatures
Similar in vivo half-life to the red blood cell
Available at a reasonable cost
Easy to administer
Able to access all areas of the human body (including ischemic tissue)
Effective on room air or ambient conditions

Perfluorocarbons

Perfluorocarbons are chemically and biologically inert artificial fluorinated organic fluids that are immiscible in water and have a high solubility for oxygen. The amount of dissolved oxygen in PFC is directly related to the ambient oxygen tension—unlike Hb, gas molecules are not chemically bound to PFC but are absorbed and released by simple diffusion. Products require oxygen inhalation by the patient, because the oxygen delivery capacity is less than 30% of normal blood. PFCs have been shown to reduce the need for RBC transfusion, but have been associated with an increase in stroke rates. Although some PFCs are still being investigated, no major trials are currently ongoing and no licensed products are available in the United States.

Hemoglobin-Based Oxygen Carriers

The stroma of the red cell causes many of the problems in allogeneic human red cell transfusions. The red cell membrane ultimately fails and limits the shelf life. The red cell membrane also contains the antigens that limit compatibility. Unfortunately, initial efforts to develop HBOCs that focused on unmodified Hb failed—unmodified tetramers naturally dissociate into dimers outside of the RBC. This unmodified tetrameric Hb is associated with renal toxicities, gastrointestinal effects, and vasoconstriction.

The HBOCs currently in clinical development are stroma-free and engineered to produce desirable oxygen dissociation characteristics as well as an adequate in vivo half-life with minimal toxicities. Stroma-free Hb has a very high oxygen affinity compared with native Hb in an RBC because of a lack of 2,3-DPG. Furthermore, the Hb tetramer is such a small molecule that the kidney rapidly removes it.

Four different methods have been suggested to avoid toxicities: stabilization, polymerization, conjugation, and Hb vesicles. HBOC can be prepared from different Hb sources. Human Hb would not alleviate supply concerns, because the amount of outdated human blood is likely to be inadequate to make large supplies of HBOC. Bovine Hb has been used as a source of hemoglobin because of its naturally low oxygen affinity and its ability to be directly polymerized (to avoid renal excretion) without prior manipulation. Bovine Hb has a molecular structure similar to human Hb but has enhanced oxygen unloading in ischemic tissue. Unlike human Hb, which is regulated by 2,3-DPG, the affinity of bovine Hb is partially regulated by serum chloride ions. Although this product removes the constraint of using human donated red blood cells, there are uncertainties about using bovine Hb because of its potential to transmit disease (e.g., bovine spongiform encephalopathy) and its potential immunogenicity.

Researchers have explored options for recombinant sources of Hb. These products are either developed in microorganisms (*Escherichia coli*, yeast) or in transgenic plants or animals. A first-generation product developed in *E. coli* was discontinued because of vasoconstrictive effects in animals. At the current time, recombinant Hb is still within preclinical development.

Two HBOC products remain in advanced clinical development: Hemopure (Biopure Corp, Cambridge, Mass) and Hemospan (Sangart, San Diego, Calif). HBOCs have recently faced significant challenges in proving their safety and efficacy in late-phase clinical trials. Hemopure has been used to treat surgical anemia in South Africa since 2001; however, since April 2011 this product has not been available.

Limitations

Several shortcomings in HBOC have emerged across the class. Although molecular size has increased enough to prevent immediate removal by the kidney, the molecules are still seen as foreign in the recipient and quickly cleared by the reticuloendothelial system. The plasma half-life is generally 24 hours or less, thus unlikely to have a role in patients with chronic anemia.

The safety of red cell substitutes remains a serious concern. Although cross-linking and polymerizing Hb subunits have reduced the incidence of nephrotoxicity, problems with vasoconstriction and pressor effects have not been completely eliminated. Vasoconstrictive responses, including increased systemic and pulmonary arterial pressures, are thought to result from the binding of nitric oxide to Hb. Free Hb is a scavenger of nitric oxide (NO); NO plays a key role in vasomotor control, specifically vasodilation, and its removal by Hb results in a vasoconstrictive effect leading to hypertension (systemic and pulmonary). In addition, Hb interaction and scavenging of NO also leads to decreased blood flow, increased release of proinflammatory mediators, a loss of platelet activation, and gastrointestinal effects, such as dysphagia.

A large metaanalysis by Natanson and colleagues identified 16 randomized controlled trials in which adult patients received HBOC therapeutically. The analysis reviewed the association between HBOC and the risk for myocardial infarction and mortality in clinical trials. The study included five different HBOCs in the analysis and reported a 30% increase in risk for death and threefold increase in risk for myocardial infarction when all HBOC trials were pooled. The metaanalysis has been criticized for including trials of varying methodologies performed on heterogeneous patient populations in different settings with different controls. The authors of the metaanalysis in turn criticized U.S. government oversight, as well as the transparency and timeliness in reporting the results of the HBOC clinical trials. The editorial that accompanied the publication of the metaanalysis in the *Journal of the American Medical Association* recommended that further Phase III trials of HBOC not be conducted until the mechanisms and potential toxicities are better understood. The effects may be due to the interaction of hemoglobin and nitric oxide, a concern not fully appreciated in the early days of blood substitute research but potentially addressed by the expansion of knowledge about NO and mitigating its effects.

In January 2009, after the metaanalysis was published, Northfield Laboratories reported the results of their multicenter controlled trial assessing survival of injured patients resuscitated with an HBOC versus intravenous fluids starting at the scene of injury. The study included 714 patients at 29 urban Level I trauma centers. No significant difference was seen in day 30 mortality between the two arms of the study. Allogeneic blood use was lower in the HBOC arm. The incidence of multiple organ failure and serious adverse events was higher in the HBOC arm, but this was not clinically significant. Although some of the data from the randomized trial suggested that the product was not inferior to transfused blood, the FDA did not approve a license application and the product is no longer being developed.

The immunogenicity of HBOC is still being studied. Because human hemoglobin has been chemically modified, it may trigger an immune response in humans. Bovine Hb has an even greater chance of causing immunogenicity in humans because of its substantial differences from the protein structure of human Hb. To date, no serious immune or allergic responses have been reported, but most patients have only had single-incident exposures to these products, usually over short periods of time. Animal studies by manufacturers have not demonstrated a problem.

Potential Clinical Applications

Red blood cell substitutes have many potential applications. One of the most compelling would be use for resuscitation during military and civilian traumas. In developing a specific plan to avoid the consequences of blood unavailability after national disasters involving large-scale injuries, blood substitutes could play a key role as an immediate treatment option. In addition to these acute emergency situations, numerous less urgent applications exist in which oxygen carriers might provide a viable solution to difficult situations, including augmenting perioperative hemodilution, transfusion of patients who refuse human blood components because of religious beliefs, transfusion of patients with rare blood types or antibodies to high incidence antigens, organ preservation for transplant surgery, and transfusion in patients with autoimmune hemolytic anemia in whom it is difficult to detect underlying antibodies.

Patients with hemoglobinopathies constitute a unique population that might receive added benefits from red cell substitutes versus donor red cells. These patients tend to be chronically transfused and also seem to be at a higher risk for becoming alloimmunized per unit transfused compared with the general population. The universal compatibility of red cell substitutes would be ideal to protect these patients from further alloimmunization and the risks of delayed hemolytic transfusion reactions.

A number of successful cases of red cell substitutes used in Jehovah's Witnesses have been reported. For religious reasons, many Jehovah's Witnesses have refused blood transfusions, even in cases of life-threatening blood loss. Fractions derived from blood are not prohibited by the religion; the decision is left to the individual as a "matter of conscience." Many Witnesses accept and even seek out blood substitutes. Severe anemia in a Jehovah's Witness makes a blood substitute a very attractive therapeutic option as a bridge to provide oxygen transport until the patient's own endogenous production can compensate for the anemia.

Patients with autoimmune hemolytic anemia are another population that may benefit from a safe and effective red blood cell substitute. It is often difficult to find compatible blood for patients with this disease because the autoantibody can make it difficult to detect coexisting alloantibodies. The universal compatibility would allow red cell substitutes to become an important bridge for patients until compatible blood could be found.

The Future of Red Cell Substitutes

Proving the benefit of red cell substitutes in clinical trials has not been easy for a number of reasons. First, in order to reduce use of donor red blood cells, we must prove that the risks presented by HBOC or PFC are not greater than those of blood transfusions. This fact has not been established. Second, without specific transfusion triggers or guidelines, it is difficult to establish whether a transfusion has actually been avoided. Finally, the goal of reducing transfusion-related expenses may not be achievable because initially, HBOCs are likely to be very expensive.

Red cell substitutes have a promising potential value for transfusion services—the increased availability of blood components and the removal of donor and contamination safety risks. However, much remains to be accomplished before these goals can be achieved; in fact, little progress has been made in recent years, and red cell substitute development may have even taken a step backwards. On the other hand, our increasing knowledge about the interactions of Hb and NO may lead to pharmacologic means to avoid some of the apparent toxicity of HBOCs.

Red Blood Cells Derived From Stem Cells

In the context of potential future blood shortages due to an increase in aging patients requiring transfusion support and a decreasing percentage of the aging population available to donate, as well as the possibility that prolonged red blood cell storage may prove to be more detrimental to a patient than beneficial, the need for a new source of red blood cells to replace the voluntary blood donor supply is urgent. Blood substitutes will not answer this need in the near future. The generation of cultured red blood cells from amplified stem cells could meet this need, and this method is currently under development by researchers worldwide.

Umbilical cord blood is an accessible source of stem cells with proliferative capacity; however, the proliferation is not infinite, requiring a system of production in batches. Giarratana and colleagues recently reported the first transfusion of cultured RBCs derived from umbilical cord stem cells into a human; the survival of the cells was similar to that of native red blood cells. Stem cells

cultured from umbilical cords would necessitate the use of cord blood banks and would still be dependent on human donation. Alternatively, embryonic stem cells and induced pluripotent stem (iPS) cells can be maintained indefinitely in culture, thus providing an unlimited source of cells. Like embryonic stem cells, iPS cells are capable of in vitro self-renewal and differentiation into cell types from all germ layers. Additionally, iPS cells possess an advantage over embryonic cells in that they pose no ethical dilemma and can be selected based on known phenotypes. Researchers have been able to demonstrate that iPS cells can differentiate into terminally mature and fully functional red blood cells. A number of challenges must be overcome before we have an unlimited supply of clinical-grade red blood cells. The ideal choice for the initial cell type (hematopoietic stem cell, erythroblast, etc.) remains to be determined. The method of reprogramming the cells must be established to avoid the risk for potential mutation and tumor development (although this is less problematic with red blood cells because they are enucleated and can be safely irradiated) while still ensuring the functionality of the end product. Finally, the use of good manufacturing process (GMP) conditions for mass amplification and production seems to be the greatest hurdle to date. Under current culture conditions, Mazurier and colleagues reported that they were able to produce only the equivalent of 1 mL of a red blood cell unit. The problem is related to the percentage of iPS cells susceptible to erythroid commitment and their amplification. A number of strategies are under development to solve this crucial problem. Until mass amplification is possible, the iPS cells could be developed, not as an unlimited supply, but as a source of cells expressing a rare blood group used to treat alloimmunized patients with rare blood types.

CHAPTER 113

PRINCIPLES OF PLATELET TRANSFUSION THERAPY

Richard M. Kaufman

PLATELET COLLECTION AND MANUFACTURING

Platelet products are either prepared from whole blood donations (platelet concentrates) or are collected by apheresis (single donor platelets [SDPs]). In the United States, whole blood–derived platelet concentrates are made using the platelet-rich plasma (PRP) method. First, a whole blood unit is separated by gentle centrifugation (slow spin) into red blood cells (RBCs) and PRP. The PRP is then centrifuged a second time (hard spin) to isolate one platelet concentrate plus one unit of plasma. Each platelet concentrate contains approximately 5.5 × 1010 platelets suspended in a plasma volume of approximately 50 mL. In Europe and Canada, the alternate buffy coat method is used to produce platelet concentrates. Platelets are stored at room temperature under continuous gentle agitation for up to 5 days. To prepare an adult dose of platelets for transfusion, four to six platelet concentrates are pooled together.

Apheresis platelet units are collected from a single platelet donor by continuous flow centrifugation using an automated device. A high volume of whole blood is processed through the machine, and the platelets are retained in a sterile collection bag. By American Association of Blood Banks (AABB) standards, an apheresis platelet unit should contain a minimum of 3 × 1011 platelets,[1] a dose that is approximately equivalent to six pooled platelet concentrates. Current devices allow many different combinations of blood products to be collected during a single apheresis donation, such as 1 unit of platelets plus 1 unit of RBCs. Apheresis platelet units generally contain less than 1 × 106 white blood cells (WBCs) per unit; thus, they meet the current AABB definition for leukoreduced blood products (<5 × 106 WBCs/unit).[1] Although apheresis platelets cost more to produce than whole blood–derived platelet concentrates, they have become increasingly popular. In the United States in 2006, approximately 1.5 million therapeutic doses of platelets were provided as apheresis platelets, and only 216,000 doses were administered as whole blood–derived platelet concentrates.[2]

Apheresis platelets provide some (limited) advantages over whole blood–derived platelet concentrates. Radiolabeling studies indicate that apheresis platelets circulate longer in vivo than pooled concentrates,[3] most likely reflecting gentler handling and less platelet activation during collection. Recipients of apheresis platelets are exposed to fewer donors per transfusion (one donor vs. six as with a pool of platelet concentrates), so in principle, apheresis platelets should pose a lower risk of viral transmission than whole blood–derived platelets. However, given that the per unit transfusion-transmission risks for HIV and hepatitis C virus have been cut to approximately one in 2,000,000,[4] the viral safety advantage of apheresis platelets over whole blood–derived platelets is marginal. Data from surveillance culture studies suggest that apheresis platelets may be less likely than platelet concentrates to become contaminated with bacteria.[3] At one time, it was predicted that apheresis platelets would be less likely than pooled concentrates to provoke platelet alloimmunization by virtue of exposing recipients to fewer unique donor human leukocyte antigens (HLAs). This hypothesis was not confirmed empirically, however.[5] Although they express surface HLA class I antigens, platelets appear to be rather poor immunogens. HLA alloimmunization to platelets primarily appears to be triggered by contaminating WBCs within a platelet unit. Thus, alloimmunization is not platelet dose dependent, and simply providing leukoreduced platelet units prevents most cases of immune-mediated platelet refractoriness.[5]

PROPHYLACTIC PLATELET TRANSFUSION

The vast majority of platelet units are transfused prophylactically to prevent bleeding in nonbleeding patients rather than to treat active bleeding. Before 1960, platelet transfusions were not widely available, and death from hemorrhage was common among patients with leukemia who received chemotherapy. In 1962, Gaydos and colleagues[6] published a seminal study demonstrating a relationship between platelet count and likelihood of bleeding. After this study was published, prophylactic platelet transfusion rapidly became standard practice. Of note, no specific platelet transfusion trigger was suggested by the authors based on their data. Regardless, a platelet count of 20,000/μL was widely adopted as the standard prophylactic platelet transfusion trigger.

Later studies suggested that a lower transfusion trigger would be as effective as a trigger of 20,000/μL. Slichter and Harker,[7] for instance, performed RBC radiolabeling studies in thrombocytopenic patients who were not receiving platelet transfusions. They demonstrated that only patients with platelet counts below 5000/μL had significantly elevated fecal RBC loss.[7] Years later, several clinical studies directly challenged the 20,000/μL trigger. Platelet transfusion triggers of 10,000/μL versus 20,000/μL were compared directly in three randomized prospective studies of patients with acute leukemia.[8-10] All of these studies, as well as large nonrandomized prospective trials,[11,12] demonstrated no increased risk of bleeding when a trigger of 10,000/μL is used.

Prophylactic Platelet Dosing

There are currently thought to be two distinct clearance mechanisms for platelets. Most platelets undergo senescence after circulating in the peripheral blood for 8 to 10 days. But there is also evidence for a second clearance route in which there is a fixed daily loss of platelets that occurs independent of platelet age. Platelets exiting the circulation via this second route are postulated to function in maintaining vascular integrity.[13] This small fixed daily platelet requirement has been estimated to be 7.1 × 109 platelets/L/day. In principle, a low dose of platelets could be used to meet this daily requirement. This hypothesis was tested directly by the Platelet Dosing (PLADO) study published in 2010. A total of 1272 patients undergoing hematopoietic stem cell (HSC) transplantation or chemotherapy were randomly assigned to receive low-, medium-, or high-dose platelets for a morning count of 10,000/μL or lower. The risk of spontaneous bleeding was not increased until patient platelet counts fell to 5,000/μL or lower. No differences were observed in bleeding rates among the three treatment groups, supporting the concept that few platelets are required to maintain hemeostasis. Although significantly fewer total platelets were transfused to patients in the low-dose group, platelet transfusions were required more frequently.[14]

Prophylactic Platelets for Invasive Bedside Procedures

At present, there have been no large randomized trials evaluating the need for platelet prophylaxis before invasive bedside procedures such as lumbar puncture. However, retrospective data provide reassurance that moderate thrombocytopenia does not pose a serious risk for performing such procedures. Howard et al[15] reviewed the records of 956 consecutive pediatric patients with newly diagnosed acute lymphoblastic leukemia who underwent lumbar puncture. No serious hemorrhagic complications were observed after 5223 lumbar punctures, including 170 procedures that were done when the platelet count was 11,000 to 20,000/μL. The authors concluded that prophylactic platelet transfusion was unnecessary in patients with platelet counts above 10,000/μL. Lumbar punctures were performed in only 29 patients with platelet counts of 10,000/μL or less, making it difficult to assess the risk of bleeding in patients with very low platelet counts. A similar, albeit much smaller, retrospective study examined the same issue in adult patients with acute leukemia.[16] No hemorrhagic complications were observed after 195 lumbar punctures, including 35 that were done with platelet counts of 20,000 to 30,000/μL. For other common bedside procedures such as central venous catheter placement, platelet counts of 20,000 to 30,000/μL are generally considered to be adequate, although, again, data from prospective studies are unavailable.

Prophylactic Platelets for Major Surgical Procedures

There are currently no data from randomized trials addressing the question of what constitutes an adequate platelet count before surgery. Retrospective studies, though, suggest that patients with platelet counts of 50,000/μL or higher are not at excess bleeding risk during surgery. Bishop and colleagues[17] reported a series of 95 patients with acute leukemia who underwent 130 surgical procedures with platelet counts of less than 50,000/μL. Intraoperative blood loss exceeded 500 mL in only 7% of cases. No relationship was seen between the preoperative platelet count and surgical blood loss. These data suggest that prophylactic platelet transfusions need not be administered before surgery when the preoperative platelet count is at least 50,000/μL. This rule of thumb is thought to apply to most types of surgery (cardiac, orthopedic, and so on). For a few types of surgeries, though, requiring a higher platelet count (70,000-100,000/μL) is traditional, although no published data currently exist either to support or refute this approach. These settings include neurosurgery, retinal surgeries, and other procedures in which the risk is not that the patient may exsanguinate but rather that even a minor bleed might cause clinically significant damage in a vulnerable vital structure such as the brain.

THERAPEUTIC PLATELET TRANSFUSION

A small number of studies published in the 1970s and early 1980s suggested the idea of using a purely therapeutic platelet transfusion strategy—transfusing platelets only to treat active bleeding rather than administering prophylactic platelets in thrombocytopenic patients. This concept was revived recently by Wandt and colleagues,[18] who reported a series of 140 HSC transplants in which no prophylactic platelets were given to clinically stable patients regardless of platelet count unless the patient had World Health Organization (WHO) grade II or higher bleeding. Patients deemed to be clinically unstable (defined as fever >38.5°C, infection, or known coagulation factor disorder) were given prophylactic platelet transfusions for platelets less than 10,000/μL. No WHO grade III or IV bleeding was observed. Grade II bleeding was seen in 26 transplants (19%). No clinically relevant bleeding was seen in the remaining 114 of 140 patients (81%). The first 60 patients in this study were compared with 60 historical control participants who were transfused with prophylactic platelets for a platelet count of less than 10,000/μL. The total number of platelets transfused was only 111 in the therapeutic group compared with 237 in the historical control group. Thus the therapeutic strategy was quite effective in this study. Randomized trials directly comparing therapeutic versus prophylactic platelet transfusion strategies are currently ongoing.

ADVERSE EFFECTS OF PLATELET TRANSFUSION

Infectious Risks

Platelets are associated with the same range of infectious pathogens as any other blood component, but septic transfusion reactions caused by bacterially contaminated units comprise a unique risk of platelet transfusion. Over time, improvements in donor screening virtually eliminated the risk of transfusion transmission of hepatitis B virus, hepatitis C virus, and HIV. The risk of septic transfusion reactions remained fairly constant over this same time period, so eventually, platelet bacterial contamination became, by default, the most frequent infectious risk of transfusion. Unlike other blood components, which are stored either refrigerated or frozen, platelets are stored at room temperature. The reason is that if platelets are refrigerated before transfusion, they are cleared rapidly from the recipient's circulation.[19] Although room temperature storage allows transfused platelets to circulate in vivo, it has the downside of promoting bacterial growth. Because of this risk, platelet storage is ordinarily limited to only 5 days, making platelet inventory management extremely challenging.

In the 1990s, numerous studies demonstrated that contaminating bacteria, usually representing skin flora from the donor, could be cultured out of approximately one of 3000 platelet units. Clinically apparent septic transfusion reactions were thought to occur after approximately 1 of 25,000 platelet transfusions, although there is considerable uncertainty around this point estimate.[20] In response to the issue, the AABB developed the following standard:

> 5.1.5.1 The blood bank or transfusion service shall have methods to limit and detect or inactivate bacteria in all platelet components. Standard 5.6.2 applies [skin disinfection].[1]

How this standard is being met varies by facility. Many blood collection centers have begun routinely culturing platelet units using an automated culture system. The BacT/ALERT system (BioMerieux), used by many centers, works by continuously monitoring for bacterial production of CO_2 within culture bottles. Platelet units are sampled on the day after collection. The samples are cultured for a period of time, typically 24 hours, and if the cultures fail to produce abnormal levels of CO_2, the product is released into inventory. Overall, culture-based bacterial screening appears to have decreased, but not eliminated, the risk of septic reactions.[21] Rapid, point-of-issue tests that can be used to test the sterility of a platelet unit just before issue have also been developed. Reducing the bacterial risk further may ultimately require alternative approaches, such as pathogen reduction. Pathogen inactivation systems, using photosensitive dyes or ultraviolet (UV) light, can provide up to 6 logs of killing of spiked virus or bacteria within 1 unit of platelets or RBCs. Although such systems have been used in Europe and elsewhere, at this time, no pathogen inactivation system is licensed for use in the United States.

Allergic and Febrile Nonhemolytic Transfusion Reactions

The typical RBC unit contains approximately 20 mL of plasma. Platelet units contain far more plasma, approximately 200 mL on average. There are multiple potential adverse effects associated with this large plasma content. First, allergic transfusion reactions are frequently associated with platelet transfusion. Allergic reactions to platelet transfusions occur when the recipient has a preexisting allergy to a plasma protein component. Allergic reactions can range from mild, uncomplicated urticarial reactions to full-blown anaphylaxis.

Febrile nonhemolytic reactions, defined as an increase in temperature of more than 1°C, may also be seen after platelet transfusion. In an elegant study, Heddle and colleagues[22] demonstrated that the plasma component of platelet units, rather than the cellular component, causes most reactions. Cytokines that accumulate during product storage have been implicated.

ABO and Hemolytic Reactions to Platelets

Whenever possible, platelet units are assigned so as to match the donor plasma with recipient RBC type. For example, a type A patient would ordinarily receive type A or AB platelets, which do not contain anti-A antibody. When platelet inventories are constrained, however, it is a frequent practice to provide ABO-incompatible platelets. For example, a type A patient can receive type O platelets, containing anti-A. The passive transfusion of donor anti-A or anti-B to a patient rarely results in a clinically apparent reaction. Occasionally, however, hemolysis may be observed. Most often, this occurs with units from type O donors, who occasionally have high titer anti-A, anti-B, or anti-A,B antibody. In a typical type O adult, the titer of circulating anti-A is on the order of one in 128 to one in 256. Some donors, for unclear reasons, have anti-A titers of one in 10,000 or higher. Recipients of products from donors with high-titer anti-A (and less frequently, anti-B) rarely do have clinically apparent hemolysis, and a small number of fatalities have been reported. This is considered to be a low-risk event, but it may be on the rise in the United States because of the increased number of single-donor apheresis platelet units used. One strategy to deal with this issue is to measure the anti-A/B titer on all platelet donors; components exceeding a threshold titer are assigned to type-specific recipients. An alternate strategy is to gently reduce the load of plasma in a platelet unit before transfusing the unit to a non–ABO-identical recipient.

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) is an acute respiratory distress syndrome associated with the transfusion of any plasma-containing blood component, including platelets. Most cases of TRALI appear to be precipitated by the passive transfusion of donor anti-HLA or (less commonly) antineutrophil antibody. It is believed that products containing higher volumes of plasma such as fresh-frozen plasma (FFP) and apheresis platelets carry a higher risk of TRALI. Approximately one-third of female blood donors have circulating anti-HLA antibody because of prior sensitization during pregnancy. To help mitigate against the risk of TRALI, many countries, including the United States, now produce FFP from the blood of male donors only. Although this strategy has been relatively easy to apply to FFP production, female platelet donors are still needed to ensure an adequate platelet supply. A variety of strategies are being implemented to screen female platelet donors for anti-HLA antibody and to defer women who are antibody positive.

Rh(D) Sensitization

The Rh(D) antigen is the most immunogenic RBC protein antigen. More than 80% of individuals who are Rh(D) negative will form an anti-D antibody after a single Rh(D)-positive RBC transfusion.[23] Anti-D antibodies are associated with both hemolytic transfusion reactions and hemolytic disease of the fetus and newborn. For this reason, it is standard practice to provide Rh(D)-negative individuals exclusively with Rh(D)-negative RBC units. Platelet units contain a small number of contaminating RBCs. In the case of platelet concentrates, approximately 0.3 to 0.5 mL RBCs may be present. Current apheresis platelets contain far fewer RBCs (≈0.0002 to 0.0007 mL per unit). Ordinarily, Rh(D)-negative platelet units are given to Rh(D)-negative recipients. However, inventory constraints frequently force blood banks to provide Rh(D)-positive platelet products to Rh(D)-negative recipients. Transfusion of such units is associated with a low but nonzero risk of sensitization and formation of anti-D. Anti-D antibody formation can be prevented by administering Rh immune globulin, as is done to prevent fetomaternal Rh sensitization in Rh(D)-negative mothers of Rh(D)-positive children. The risk of sensitization is especially low among Rh(D)-negative immunocompromised patients transfused with Rh(D)-positive platelets (e.g., hematopoietic stem cell transplantation patients). In this setting, the value of Rh immune globulin (RhIG) prophylaxis appears to be marginal.

PLATELET REFRACTORINESS

Causes of Refractoriness to Platelet Transfusion

Platelet refractoriness is defined as an inappropriately low platelet increment after repeated platelet transfusions. It can be caused by nonimmune or immune factors (Table 113-1). The most commonly reported nonimmune causes of platelet refractoriness include fever, sepsis, bleeding, splenomegaly, and disseminated intravascular coagulation. In a subset of cases, platelet refractoriness is immune mediated. Platelets express HLA class I antigens, ABO antigens, and several platelet-specific antigens. Any of these molecules may potentially serve as an immune stimulus in a transfusion recipient. Whereas antibodies directed against HLA molecules are responsible for most cases of immune-mediated platelet refractoriness, antibodies to the human platelet antigens (anti-HPA antibodies) are less frequently implicated.

Diagnosis of Platelet Refractoriness

Because fewer than half of all platelet-refractory patients have demonstrable anti-HLA or antiplatelet antibodies,[24] evaluation of both an immediate response to platelet transfusion and an 18- to 24-hour posttransfusion platelet survival is needed to help establish the cause of platelet refractoriness. Platelet counts obtained from 10 minutes to 1 hour after transfusion that repeatedly fail to demonstrate a corrected count increment of more than 5000/μL usually indicate immune-mediated platelet refractoriness.[25] If the 10-minute to 1-hour posttransfusion platelet count shows a reasonable increment but the platelet count falls back to baseline by 18 to 24 hours, a nonimmune mechanism of refractoriness may be presumed (see Table 113-1). In cases of suspected immune-mediated refractoriness, HLA antibody screening (panel reactive antibody [PRA]) provides valuable supporting evidence that allosensitization has occurred.[26] A patient with a PRA greater than 70% may be considered to be "severely immunized" and a good candidate for HLA-matched platelets (below).

Table 113-1 Causes of Refractoriness to Platelet Transfusion

Immune
Anti-HLA antibodies
Anti-HPA antibodies
ABO mismatch
Drug-dependent antibodies

HLA, Human leukocyte antigen; *HPA,* human platelet antigen.

Detection of Anti–Human Leukocyte Antigen Antibodies

Several assays are available to detect the presence of anti-HLA class I antibodies in the serum of alloimmunized patients. Years ago, the most commonly used test was the lymphocytotoxicity assay (LCA). The results of the LCA correlate well with the response to platelet transfusion. However, this assay does not detect anti-HLA antibodies that do not activate complement. The anti-HLA antibodies can also be detected using an HLA-specific solid-phase enzyme-linked immunosorbent assay, glycoprotein-specific monoclonal antibody-specific immobilization of platelet antigens, or flow cytometric detection of antibody binding to beads coated with purified HLA antigens. The flow cytometry–based methodology has significantly improved sensitivity over LCA and, similar to solid-phase assays, it can detect both complement-fixing and non–complement-fixing antibodies.[27]

Detection of Antiplatelet Antibodies

The most commonly used methods for detection of anti-HPA antibodies are solid-phase assays using purified platelet antigens for detection of antibody specificity. However, testing for anti-HPA antibodies is not typically performed in the workup of platelet refractory patients, mainly because the importance of these antibodies in causing clinical refractoriness is not well established.

Prevention of Alloimmunization

Although they express HLA class I antigens, platelets themselves are fairly weak immunogens. It has been shown that contaminating leukocytes in platelet products are primarily responsible for stimulating HLA antibody formation in platelet transfusion recipients.[28] Thus removing WBCs from blood products (leukoreduction) is an essential means of preventing alloimmunization and subsequent platelet refractoriness. The definitive study showing this was the Trial to Reduce Alloimmunization to Platelets (TRAP study),[5] which compared alloimmunization rates in 530 newly diagnosed patients with acute myeloid leukemia randomized to receive unmodified, pooled platelet concentrates (control); filtered, pooled platelet concentrates (F-PC); filtered single-donor apheresis platelets (F-AP); or UV-B-irradiated pooled platelet concentrates (UVB-PC). Anti-HLA antibodies were detected in 45% of control participants compared with 17% to 21% of patients receiving modified platelets. A total of 13% of control group patients became platelet refractory versus only 3% in the F-PC group, 4% in the F-AP group, and 5% in the UVB-PC group.

Management of Platelet-Refractory Patients

When platelet refractoriness has been demonstrated, several strategies may facilitate achieving therapeutic platelet increments in vivo (Table 113-2). A trial of ABO-matched, fresh (1-2 days old) platelets may be helpful. In cases of immune-mediated refractoriness, a trial of HLA-matched platelets,[29] antigen-negative platelets, or crossmatched platelets should be considered. The basic principles for selection of HLA-matched platelets are outlined in Table 113-3. In most cases, alloimmune refractory patients will show some degree of response to HLA-matched platelets.[30] Because of the high degree of polymorphism of the HLA loci, it is often not possible to find perfect HLA-A and -B locus matches, leading to the use of platelets mismatched at one or more loci (Table 113-4). In general, transfusion of grade A- or BU-matched platelets can result in an increase in platelet count that is superior to platelet increment obtained using either crossmatched platelets or platelets with different degrees of HLA mismatching (BX, C, or D). Examples of different categories of matches are provided in Figure 113-1. An additional step that may help in finding compatible platelets is flow cytometric detection of anti-HLA antibody specificity using single HLA antigen–coated beads. This information can be used to find donors that may be HLA mismatched with the recipient but whose platelets lack the antigens to which the patient has specific antibodies. Furthermore, family members may be considered as platelet donors in addition to the available pool of HLA-matched volunteer donors. As an alternative to HLA antigen matching, patients may benefit from receiving donor platelets that are crossmatch compatible with the patient's serum. The major benefit of crossmatching is a potentially larger pool of donors that would have been excluded by strict HLA antigen matching. Also, platelet crossmatching may be helpful in cases of refractoriness caused by antibodies directed against platelet-specific antigens.

The most challenging cases are the rare instances involving immune-refractory patients who are actively bleeding and HLA-matched platelets or crossmatched platelets are either ineffective or

Table 113-2 Management of the Platelet-Refractory Patient

Obtain 10-minute to 1-hour posttransfusion platelet count on two occasions.
If there is an appropriate increment in platelet count after a single platelet transfusion, continue to transfuse random platelets and treat nonimmune factors associated with decreased platelet survival such as sepsis and DIC, discontinue offending drugs, and so on.
If the 10-minute to 1-hour posttransfusion platelet counts demonstrate no platelet increment (or only a marginal increment), obtain the patient's HLA type and screen the patient for the presence of anti-HLA antibodies (panel reactive antibody test).
While awaiting HLA antigen typing and antibody screening results, consider transfusion of "fresh" (<3 days old) ABO-matched platelets.
If PRA shows less than 20% reactivity, continue with "fresh" ABO-matched random platelets.
If PRA shows more than 20% reactivity, obtain anti-HLA antibody specificity. Use the recipient's HLA typing information to locate grade A or B matched platelet units for transfusion. Avoid transfusion of platelets containing antigens against which the recipient has antibodies. Consider recruiting recipient's family for platelet donation.
Transfusion of crossmatch-compatible platelets is an option if there is a poor response to grade A- or B-matched platelets or if the recipient has antibodies to platelet-specific antigens.
All HLA-matched or crossmatched platelet units must be irradiated before transfusion to prevent transfusion-associated GVHD.

DIC, Disseminated intravascular coagulation; *GVHD,* graft-versus-host disease; *HLA,* human leukocyte antigen; *PRA,* panel reactive antibody.

Table 113-3 Traditional Platelet Selection Guidelines for Refractoriness Caused by Alloimmunization

ABO antigens are expressed on platelets. Consider transfusion of ABO-matched platelets while awaiting the recipient's HLA type and antibody specificity
Platelet matching for the recipient's HLA A and HLA B antigens is important.
Platelet matching for the recipient's HLA C antigens is not essential.
Determine the antigen specificity of recipient's antiplatelet antibodies and try to transfuse antigen negative platelets.
Some HLA antigens may be weakly expressed on platelets. Consider giving platelets mismatched for those antigens (e.g., HLA B12 and its splits B44, B45)
If HLA-matched platelets are unavailable, consider transfusion of platelets mismatched for HLA antigens that are serologically cross-reactive with the recipient's HLA antigens.
If platelets mismatched for serologically cross-reactive antigens are not effective, matching for HLA-associated antigen systems such as Bw4/Bw6 may be helpful.

HLA, Human leukocyte antigen.

Table 113-4 Grades of Human Leukocyte Antigen–Matched Platelets

Match Grade	Description
A	4-antigen match (donor and recipient match at both HLA-A and -B loci)
B1U	1 antigen unknown or blank (e.g., donor is: A2, –; B5, 27)
B1X	1 cross-reactive group*
B2UX	1 antigen blank and 1 cross-reactive*
C	1 mismatched antigen present
D	≥2 mismatched antigens present
R	Random

CHAPTER 114

HUMAN LEUKOCYTE ANTIGEN AND HUMAN NEUTROPHIL ANTIGEN SYSTEMS

Ena Wang, Sharon Adams, David F. Stroncek, and Francesco M. Marincola

This chapter reviews human leukocyte antigen (HLA) and human neutrophil antigen (HNA) systems. A general background of the structure, function, and nomenclature of both systems and their relevance in clinical hematology is presented. Analysis of HLA gene products is applied in clinical settings (1) to select compatible donor-recipient pairs for transplantation, (2) to select HLA-compatible single-donor platelet products for thrombocytopenic patients refractory to standard transfusion of random pooled platelets, (3) to screen for genetic factors that may contribute to the prevalence of diseases, and (4) for forensic purposes in which the identity of individuals may contribute to solving legal disputes or criminal investigations. In addition, we discuss new applications that have broadened the relevance of HLA in the area of immune pathology. HLA phenotypes determine the suitability of patients for epitope-specific immunization. Tetrameric HLA/epitope complexes (tHLA) allow enumeration of antigen-specific T-cell responses. Furthermore, molecular identification of T-cell epitopes associated with distinct diseases and characterization of the communication between immune effector cells through HLA–HLA ligand interactions extend the relevance of HLA to biologic fields. These biologic fields encompass natural killer (NK) and cytotoxic T-cell function, antigen recognition in the context of infection, autoimmunity, graft-versus-neoplasia (GVN) effect, and autologous cancer rejection. Finally, the recognition that polymorphism extends to other protein families relevant to immune pathology including cytokines, their receptors, and killer cell–inhibitory receptors has broadened the significance of immunogenetics beyond HLA. Thus this chapter emphasizes the importance of viewing human pathologic conditions through the kaleidoscopic complexity of human polymorphism.

GENETICS, STRUCTURE, AND FUNCTION OF HLA MOLECULES

HLAs embrace a family of genes clustered in the short arm of chromosome 6 as the human version of the major histocompatibility complex (MHC), initially identified in mice as responsible for graft rejection between genetically unrelated strains (transplantation antigens).[1] Credit for the description of the human MHC goes to three individuals. In 1952, Jean Dausset observed that serum of individuals who had received several transfusions contained hemagglutinins specific for donors' leukocytes. In 1958, Rose Payne noted that the only requirement for the development of hemagglutinins against leukocytes was a history of previous transfusion or pregnancy and concluded that these antibodies were directed against antigens on the surface of circulating leukocytes. This conclusion was concomitantly and independently confirmed by Jon van Rood, who observed that multiple pregnancies immunize mothers against leukocytes leaked from the fetus into the mother's circulation. Based on these discoveries, the term *human leukocyte antigen* was subsequently adopted.[2] It should be clarified, however, that this historical name is misleading. Neither is HLA molecule expression limited to leukocytes nor do they display, in natural conditions, antigenic behavior. In fact, several are expressed by most somatic cells, and, rather than being antigens, they chaperone protein bioproducts to the cell surface for recognition by T cells. There is, however, some substance to the name, because HLAs, by virtue of being densely packed on the cell surface, are exposed to recognition in a foreign environment such as allotransplantation or xenoinfusion performed to induce anti-HLA antibodies as diagnostic reagents.

ORGANIZATION OF THE HLA GENES

HLA genes constitute a string of coding sequences that regulate the expression of molecules with similar but not identical function. Residing in a region that spans approximately 4000 kilobases of the short arm of chromosome 6 (Fig. 114-1),[3] HLA contains several genes and pseudogenes characterized by sequence homology and functional similarity. Of them, 47 are officially recognized by the World Health Organization nomenclature committee[4] and include classic HLA class I and class II genes associated with antigen processing such as PSMB8 and PSMB9 (proteasomal units) or TAP1 and TAP2 associated with peptide transport. Both HLA and HLA-associated genes can be physically grouped into three subregions according to chromosomal location. In centromeric to telomeric direction, the first is HLA class II region comprising the α-and β-chains of HLA-DR, -DQ, -DP, -DM, and -DO as well as TAP and PSMB. Sandwiched between the class II and class I region, class III region encodes for functionally unrelated genes such as complement components, heat shock proteins, and tumor necrosis factor. The reason for their genetic link to the HLA complex is unknown, but their immunologic function seems more than coincidental. The class I region is most telomeric and includes HLA-A, -B, and -Cw loci; the nonclassic HLA-E, -F, and -G loci; and several pseudogenes.

General terminology separates HLA genes into classic and nonclassic. Classic HLA genes have been well characterized and are clearly associated with presentation of antigen to immune cells. They are further subdivided into class I (HLA-A, -B, -C) and class II (HLA-DR, -DQ, and -DP). In general, HLA class I and II genes have very similar structure and function.[5,6] They contain six to eight exons coding for functionally distinct domains (Fig. 114-2). The first exon encodes a leader sequence; the following exons (exons 2 to 4) are highly polymorphic and encode extracellular domains responsible for peptide binding and T cell–antigen receptor (TCR) engagement. Because they are exposed on the cell surface, these domains are also responsible for alloreactivity. The last exons encode a conserved transmembrane and small intracellular domains whose function is unclear.

Only the heavy chain of HLA class I is encoded in the MHC region. Genes encoding HLA-A, -B, and-C contain three exons coding for α_1, α_2, and α_3 extracytoplasmic domains, one transmembrane, and three cytoplasmic domains (Fig. 114-3). The associated class I light chain, β_2-microglobulin, is encoded on chromosome 15.[7] By contrast, the HLA class II molecule is composed of a heterodimer of an α-chain and a β-chain encoded in the MHC region. Although the genetics are different, the protein product is structurally similar to HLA class I, with two helices resulting in the antigen-presenting part of the molecule (Fig. 114-4).

All DR molecules use DRA for α-chains but can use alleles coded by DRB1, DRB3, DRB4, or DRB5 for β-chains. DP, DQ, DM, and DO molecules are the product of DPA1 and DPB1, DQA1 and DQB1, DMA and DMB, and DOA and DOB genes, respectively.

HLA DRB1 locus is expressed in all HLA haplotypes (the set of HLA alleles derived from the same parental chromosome and therefore genetically linked). However, only one other HLA DR locus is present in each individual chromosome. Thus each haplotype can have either DRB5 (DR1 haplotype); DRB3, -B4, or -B5 loci (DR2 haplotype); DRB4 locus (DR4 and DR7 haplotype); or none (DR8 and DR10 haplotype).[3]

INHERITANCE AND LINKAGE DISEQUILIBRIUM

Because of their proximity within a short chromosomal distance, HLA genes are inherited en bloc from each parent unless a

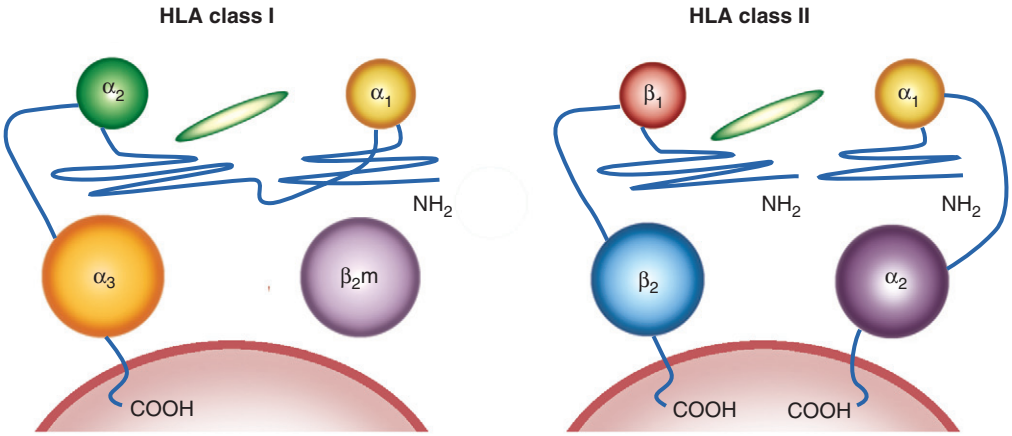

Figure 114-4 SCHEMATIC DIAGRAM OF HUMAN LEUKOCYTE ANTIGEN (HLA) CLASS I AND CLASS II MOLECULES POINTING TO THEIR STRUCTURAL SIMILARITY. In both HLA classes, two immunoglobulin-type domains reside close to the cell membrane (α_3 and β_2m for class I and α_2 and β_2 for class II). The other two domains project toward the extracellular milieu with α-helices (α_1 and α_2 for class I and α_1 and β_1 for class II) and a platform of parallel β-sheets that form a peptide-binding groove.

recombinant event occurs. Thus each HLA haplotype behaves as a unit and is transmitted through generations according to mendelian principles. Because there are four possible genotypes (two from each parent), the probability of genotypic identity between two siblings is 25%. Most HLA phenotypically identical siblings are also HLA genotypically identical, because the genetic pool of derivation is restricted to the parents. In 2% of cases, recombinant HLA haplotypes (a set of genes derived partially from two chromosomes through recombination) deviate from this rule.

The occurrence of HLA haplotypes within a population with a frequency higher than expected from the prevalence of individual alleles is called *linkage disequilibrium.* In large populations, gene frequencies achieve equilibrium within a few generations unless selective pressure influences individuals' survival and mating capacity (Hardy-Weinberg principle). In equilibrium, gene prevalence is maintained based solely on its frequency. Thus, assuming that there were 18, 36, and 8 alleles for the HLA-A, -B, and -C loci, respectively (number of alleles known when this example was described[2]), theoretically $18 \times 36 \times 8 = 5184$ HLA class I allelic combinations or haplotypes would be possible. Adding HLA class II genes to the calculation yields an astronomical number, making unlikely the identification of two HLA-matched individuals. However, individual alleles occur with different frequency, and an allele that occurs with high frequency is predominant in a given population, such as HLA-A2 in whites and A24 or A11 in Asians.[8] Because predominant alleles come with the related haplotype, most theoretical permutations never occur, and the chances of identifying matched individuals are much higher than theoretically possible.

STRUCTURE OF THE HLA CLASS I AND II

The structure of HLA molecules and their relationship with their natural ligand, the TCR, has been well characterized by crystallography.[9-11] HLA molecules are heterodimer glycoproteins belonging to the immunoglobulin superfamily with common features (see Fig.114-4). This includes two α-helical domains protruding toward the extracellular milieu. Between them lies a flat surface formed by β-sheet structures that contributes to the formation of a groove accommodating peptides generated from intracellular (HLA class I) or extracellular proteins (HLA class II) (Fig. 114-5). The helices/peptide complex is exposed for TCR recognition. Because HLA polymorphism is clustered within the α-helixes and β-sheets domains, peptides display variable affinity for distinct HLA alleles.[12,13] It has been proposed that a given peptide can bind to closely related alleles, and HLA superfamilies with similar binding characteristics have been described.[14-16] However, peptide binding to related but distinct HLA alleles is associated with conformational dissimilarity caused by differential interaction with variant residues in the binding groove.[17] The TCR interaction with HLA required for productive engagement spans a surface including the peptide and portions of the α- and β-helix.[11,18-20] This double requirement of interaction between TCR and HLA/peptide complex represents the structural basis for HLA restriction. Degenerate and promiscuous TCR recognition of peptides presented by distinct HLA alleles within the same superfamily has also been described.[21] Although this concept holds in general, several exceptions can be expected because single amino acid variants in the HLA molecule may disallow binding of a peptide[22] or may not be permissive to TCR engagement.[23,24]

The binding affinity of a given peptide for an HLA allele can be predicted through algorithms that compile available information to

identify amino acid residues that fit distinct pockets of the HLA groove.[12,25] Several algorithms implement this information with experimental testing based on the refolding capability of HLA heavy chains exposed to known peptide sequences in the presence of β_2-microglobulin and/or their dissociation rates (see www.bimas.dcrt.nih.gov or www.uni-tuebingen.de/uni/kxi). This is based on the principle that the affinity of a peptide for a given HLA promotes that stability of the noncovalent assembly of heavy chain with β_2-microglobulin.[12,26] Finally, peptide binding can be shown by direct elutriation from purified HLA heavy chains.[13,27]

Beyond the interactive component of the HLA molecule with TCR, other domains act as coreceptors for the TCR. $CD8^+$ cytotoxic T cells bind to the α_3-domain of HLA class I through CD8, whereas $CD4^+$ T cells interact with HLA class II–specific domains. Although the coreceptor-TCR interaction is not an absolute requirement in most cases, it determines HLA class I or II restriction of individual T cells.[28]

Specific to HLA class I is the assembly with β_2-microglobulin on stabilization in the presence of high-affinity peptides derived from the cleavage of intracellular proteins (endogenous pathway of antigen presentation).[29] Most peptides derive from degradation of self-protein in the cytosol by proteasomes (PSMB) and other proteases.[30] Soluble peptides (9 to 10 amino acids long) are then chaperoned into the endosomal compartment by transporter molecules associated with antigen processing (TAP1 and TAP2). Within this compartment, they bind to heavy chains according to each individual's HLA phenotype. The binding and stability of the HLA-peptide complex depends on the affinity of each peptide for a particular allele. If the stability is sufficient, the peptide-loaded HLA migrates to the cell surface. Intracellular pathogens produce proteins that are also degraded by proteasomes into peptides that compete with self-peptides for binding to HLA class I molecules. Thus the function of the endogenous pathway of antigen presentation is to provide information to the extracellular compartment of intracellular events. In physiologic conditions, only self-peptides are presented, and therefore minimal interactions occur with circulating T cells. During infection, pathogen-derived peptides signal cellular infection to T cells, whereas antibodies that cannot cross the cell membrane remain insensitive to intracellular pathogens. Several pathogens, such as cytomegalovirus, can interfere with this process as well as with reduction of HLA/peptide density on the cell surface and, consequently, diminished T-cell recognition.[31,32] This escape mechanism can be counteracted by the host through increased susceptibility of virally infected cells to NK cell–mediated cytolysis.[33] Reciprocally, viruses can evade NK cells and escape recognition by modulating HLA expression.[34-36]

HLA class II molecules bind to longer peptides derived from the metabolism of molecules endocytosed from the extracellular compartment (exogenous pathway of antigen presentation).[29] This is a specialized process used by professional antigen-presenting cells such as macrophages and dendritic cells. HLA class II molecules are assembled within the endosomal compartment where they are composed of a heterotrimer. This includes the α- and β-chains plus a short invariant chain that stabilizes the molecule by occupying its groove while chaperoning its migration to the endosomal compartment where exogenous antigen is processed. Upon uptake, the exogenous antigen undergoes limited proteolysis in the membrane-bound acidic endosomal compartment (MHC class II peptide-loading compartment, MIIC). Upon entering the MIIC, the pre-HLA class II complex is degraded, and antigenic peptides are loaded with the help of the nonclassic HLA-DM molecule.[37]

EXPRESSION OF HLA MOLECULES

There are genetic and structural differences between the two classes of HLA alleles. The most striking difference is functional, because HLA class I molecules are expressed by most nucleated cells with the exception of germinal cells, whereas HLA class II molecules are expressed mainly by specialized antigen-presenting cells.[38,39] HLA class I molecules are also expressed by platelets.[40] They are responsible for refractoriness after multiple transfusions[41-44] and sufficiently, though minimally, expressed by reticulocytes to be targets of alloantibodies during hemolytic transfusion reactions.[45] HLA class II proteins are expressed constitutively by cells associated with the initiation of the immune response, such as monocytes, macrophages, and B cells,[46] or by immune cells activated by cytokines during inflammation. Thus HLA class I molecules instruct the host about the condition of individual cells as potential targets for $CD8^+$ cytotoxic T cells responsible for clearing the organisms of altered cells. HLA class II molecules initiate immune responses by taking up pathogen components and presenting them to $CD4^+$ helper T cells, which can in turn initiate humoral and facilitate cellular immune responses.

Expression of HLA alleles is sensitive to environmental conditions and can be modulated by cytokines among which interferons play a major role.[47] This is particularly important for HLA-B and HLA-C normally expressed at a lower density than HLA-A but which are more sensitive to cytokine induction.[48,49] In addition, HLA class II molecules can be expressed by most cells following cytokine stimulation.[50,51] Thus the ability of cells to present antigen in association with HLA is strongly influenced by the surrounding environment. This might explain why chronic inflammation induced by alloreactions during graft-versus-host disease (GVHD) may facilitate the presentation of tumor-specific antigens by tumor cells with consequent development of GVN effect. In addition, it might explain how systemic administration of proinflammatory cytokines such as interleukin-2 may stimulate immune responses by increasing the antigen-presenting ability of cells within the tumor microenvironment.[52]

HLA POLYMORPHISM AND ITS CLINICAL SIGNIFICANCE

A striking characteristic of the HLA system is its extreme polymorphism.[53] By chance, most individuals are heterozygote and therefore carry two different alleles for each HLA gene that, being codominant, are equally expressed on the cell surface. Because everybody carries three HLA class I (-A,-B, and -C) and three HLA class II (-DR, -DQ, and -DP) genes, most individuals (with the exception of homozygotes) express six different HLA class I and six different HLA class II molecules on the surface of their cells. This has important functional implications, because HLA polymorphism is clustered in domains of the HLA molecule associated the peptide binding and interaction with the TCR. Thus most individuals have a broad repertoire of molecules capable of presenting different pathogen components to immune cells. Therefore it is believed that HLA polymorphism improves the chances of a given species of surviving infection.[54] This paradigm is difficult to demonstrate in human pathologic conditions in which the natural history of infectious diseases rarely correlates with HLA phenotype. An exception is the strong association between HLA-B*5701 and lack of progression to acquired immunodeficiency syndrome of individuals infected with human immunodeficiency virus (HIV).[55] Associations have been observed between HLA phenotype and predisposition for nasopharyngeal carcinoma.[56,57] This is of particular interest because nasopharyngeal carcinoma is a virally induced cancer against which T cells can mediate immune surveillance. HLA associations have also been described with less consistency for other virally driven tumors, such as cervical carcinoma,[58] or immunogenic tumors, such as melanoma.[59,60]

The difficulty in demonstrating conclusive associations between infectious disease and HLA in humans could be caused by the successful implementation of antigen presentation through a broad repertoire of HLA genes, which could compensate for each other in limitations in antigen presentation. Chickens carry a single MHC locus, and their susceptibility to infection appears to be clearly related to MHC. For instance, Kaufman et al[54] have shown that chickens carrying a particular Bf (the only MHC class I gene in chickens) allele are fully protected from Rous virus–induced sarcomas, because this allele (B-f12) can bind several antigenic peptides from its proteins. On the contrary, chickens homozygous for B-f4 are killed by the same infection, because this allele cannot bind peptides from sarcoma virus proteins.[54]

HLA polymorphism is the basis of alloimmunization, because most individuals are likely to have different HLA molecules on the surface of their cells. Hundreds of HLA alleles have been identified through high-resolution typing, making the chances of two individuals having identical HLA phenotypes extremely low. Thus partial mismatches are commonly accepted in transplantation cases, which are at the root of hyperacute, acute, and chronic rejections. Hyperacute rejection is caused by preformed antibodies against donor HLA alleles in patients presensitized by multiple transfusions.[61] Acute and chronic rejection result from a combination of humoral and cellular immune reactivity toward HLA alleles of the donor.[62,63] In addition to allosensitization, HLA alleles can mediate GVHD, whereby hematopoietic cells derived from the grafted tissue recognize and reject the host tissues. They do this by identifying polymorphisms of intracellular proteins of the host (minor histocompatibility antigens) presented in association with donor-recipient matched HLA alleles.

NONCLASSIC MHC AND MHC CLASS I CHAIN-RELATED MOLECULES

Besides the three ubiquitously expressed highly polymorphic classic HLA class I molecules, humans encode three relatively conserved nonclassic, selectively expressed (HLA-E, -F, and -G) MHC class I genes (also known as MHC-Ib). These evolved at different rates in primates reflecting differential involvement in the modulation of immune responses.[4,64,65] In addition, these molecules are characterized by unique patterns of transcription, protein structure, and immunologic function.[66]

The MHC class I–related chain genes (MICA and MICB) are located within the MHC region and are characterized by high polymorphism (more than 50 alleles so far identified).[67] The molecules encoded by these genes do not appear to bind peptides or associate with β_2-microglobulin. Their polymorphic variants are not concentrated around the peptide-binding groove, yet they seem to have functional significance, because most mutations are nonsynonymous, suggesting selective pressure as a driving force. Their tissue distribution is restricted to epithelial and endothelial cells and fibroblasts. It appears that MIC genes modulate the function of NK and $CD8^+$ T cells by binding the NKG2D stimulating receptor.[68] Also, MIC genes have been implicated in transplant rejection because alloantibodies against them are often found in transplant recipients that may exert complement-mediated cytotoxicity against endothelial cells from the graft.

Other unusual MHC-like molecules are present in the genome and have disparate functions, including presentation of lipid antigens (CD1), transport of immunoglobulins (Fc receptor), and regulation of iron metabolism (hemochromatosis gene product).[69] Contrary to classic MHC class I genes that are constitutively expressed, nonclassic MHC and MIC gene expression is dependent on stimulation by proinflammatory cytokines.[70] In addition, two nonclassic MHC class II proteins (HLA-DM and HLA-DO) have been described that function as mediators of peptide exchange by stabilizing empty MHC class II molecules.[37] Finally, it is possible that several nonclassic MHC molecules whose function is to present peptides to lymphocytes may be present throughout the genome. Because of their limited polymorphism, however, these genes may have evolved to serve specialized presentation functions.[71]

Characterized by low polymorphism, the regulation of HLA-G expression follows a nonclassic behavior. Aberrant cytokine-responsive regulatory sequences[72-74] may be responsible for its predominant expression by trophoblasts that do not express other HLA proteins.[75] It may also account for its low levels in a variety of human tissues.[76] Lack of responsiveness to common immunostimulatory pathways (NF-κB, interferon-γ, or CIITA) is most pronounced in HLA-G cells and is shared by other nonclassic MHC such as HLA-E.[77] Also, HLA-G is expressed in a variety of cancers.[72] It is hard to know what the relevance of HLA-G expression is, because it can occur in various membrane-bound or soluble isoforms with distinct functional characteristics.[72] Functional isoforms that include the α-1 and α-2 domains bind and present peptides from cytoplasmic proteins.[78] Because of the minimal polymorphism, however, the repertoire of peptides presented is likely to be limited, suggesting that peptide binding is necessary to stabilize the molecule rather than being involved in antigen presentation.

Functionally, HLA-G is thought to modulate the function of NK cells through interactions with their inhibitory receptors.[79] In addition, the HLA-G leader sequence contains a peptide that can bind and stabilize the expression of HLA-E, which, in turn, inhibits NK cells.[80] Because the HLA-G–derived leader peptide has the strongest affinity for HLA-E (among all HLA class I molecules), it is likely that HLA-G is a powerful direct and indirect inhibitor of NK cells, reducing the risk for cardiac rejection[81] or inducing immune escape of cancer cells.[72] Although much has been published about the immunoregulatory role of HLA-G, its true function remains mysterious, principally because of discordant findings reported by various groups.[73] With the goal of achieving consensus, a workshop was recently organized to standardize methods of analysis of HLA-G.[66]

HLA-E is minimally polymorphic,[4] binds hydrophobic peptides from other HLA class I leader sequences, and interacts with CD94/NKG2 lectin-like receptors present predominately on NK and partially on $CD8^+$ T cells.[82-85] The peptide binding is highly specific and stabilizes the HLA-E protein, allowing its migration to the cell surface. Thus surface density of HLA-E is an indirect reflection of the number of HLA class I alleles expressed by a cell.[86] The interaction of HLA-E with CD94/NKG2 protects HLA-E–expressing cells from killing. Cells damaged by viral infection or neoplastic degeneration may lose HLA class I expression. As a backup mechanism of protection, reduced HLA class I expression results in decreased expression of HLA-E, leading to vulnerability to NK cells.[87] Some viruses express mimic peptides that bind and stabilize HLA-E so that, although classic MHC molecules are downregulated, HLA-E expression is maintained, allowing the pathogen to simultaneously escape $CD8^+$ T- and NK-cell killing.[88]

The function of HLA-F remains enigmatic. Its transcriptional regulation is closest to classic HLA molecules in that it can be induced by NF-κB, interferon regulatory factor-1, and class II trans-activator.[89] However, contrary to classic HLA molecules, HLA-F is predominantly empty, mostly intracellular, with a restricted pattern of expression.[90] Its tissue distribution appears to be limited to B cells, and therefore it is mostly found in lymphatic organs.[90] Structural studies suggest that HLA-F is a peptide-binding molecule and may reach the cell surface under favorable conditions when a suitable peptide is present.[91] Once on the cell surface, HLA-F may interact with the effector-cell receptors IL-T2 and IL-T4, as suggested by HLA-F tetrameric complexes–binding studies.[91] Thus it is possible that in specific yet unknown conditions, HLA-F may modulate the function of immune effector cells similarly to HLA-E and HLA-G.

NON-HLA POLYMORPHISM AND ITS CLINICAL SIGNIFICANCE

Although this chapter is dedicated to HLA, it would be incomplete without mentioning the increasingly recognized polymorphisms of other immune modulators. The significance of non-HLA polymorphism is evidenced by the development of GVHD in the presence of HLA identical matching among relatives. As recently summarized,[92] three general areas of polymorphism are being investigated: NK cell–receptor genes, minor histocompatibility antigens, and cytokines. Over the last decade, much progress has been made in identifying the mechanisms of action of NK cells. A major breakthrough was made in the discovery of HLA class I–specific inhibitory receptors and in the role that they play in the regulation of NK function with consequent effects on the eradication of hematologic malignancies, prevention of graft rejection, or induction of GVHD.[93] NK cells recognize HLA molecules via killer immunoglobulin-like receptors (KIRs). The regulation of NK cell function by KIRs is further

Table 114-1 HLA Class I Alleles Recognized by Different Killer Immunoglobulin-Like Receptors

KIR	HLA Class I Allele	Amino Acid Sequence Motif
P58.1 (KIR2DL1)	HLA-C2, -C4, -C5, -C6	Asn 77, Lys 80

(KIR2DL4)	HLA-G	

Aa, Amino acid; *Asn,* asparagine; *HLA,* human leukocyte antigen; *KIR,* killer immunoglobulin-like receptor; *Lys,* lysine; *Ser,* serine.

discussed in Chapter 12. KIRs are glycoproteins encoded by at least 17 different genes located on chromosome 19q13.4.[94] All human KIR genes derive from a gene encoding three immunoglobulin (Ig)-like domains (D0, D1, and D2) and a long cytoplasmic tail. However, the KIRs genes are diverse and may encode either two or three Ig-like domains and either a long or short cytoplasmic tail (Table 114-1). The long cytoplasmic tails contain one or two immunoreceptor tyrosine-based inhibition motifs.[95] Although KIR molecules with long cytoplasmic tails inhibit NK cytotoxicity, those with short tails do not. The names given to KIR genes are based on the molecule that they encode. The first digit corresponds to the number of Ig-like domains in the molecule and a *D* denotes domain. The D is followed by either an *L* for long cytoplasmic tail or *S* for short cytoplasmic tail or *p* for a pseudogene. The last digit indicates the number of the KIR gene.[96]

Expression of KIR in individual NK cells is complex because NK cells may express several members of the KIR family. The number of KIR genes in each haplotype varies among individuals. The most common haplotype is known as group A, which is made up of six genes (2DL1, 2DL2 or 2DL3, 3DL1, 3DL2, 2DS4, and 2DL4). Various KIR genes can recognize different HLA-A, HLA-B, and HLA-C molecules. HLA-C antigens can be divided into two groups based on polymorphisms at amino acid positions 77 and 80 of their class I heavy chains. One group has asparagine (Asn) at position 77 and lysine (Lys) at 80 and the other has serine (Ser) at 77 and Asn at 80. Some KIRs recognize HLA-C antigens with Asn 77 and Lys 80, whereas other KIRs recognize HLA-C antigens with Ser 77 and Lys 80. The polymorphism at position 80 is most important. Another group of KIR reacts with HLA-B antigens that carry specific combinations of amino acids at positions 77 and 83 of the heavy chain that forms HLA-Bw4. Because a single KIR can interact with multiple HLA class I alleles, KIR recognition of HLA class I molecules is degenerate. Another NK inhibitory receptor (CD94-NKG2A) recognizes the nonclassical HLA-E molecule. In addition, each of the KIR genes is extensively polymorphic.

Because the genes for KIR, HLA, and CD94-NKG2A are located in separate chromosomes, they segregate independently and consequently individuals can carry genes for KIR for which there is no correspondent HLA ligand.[97] Because HLA-E is expressed in all individuals, NK cells that bear the CD94-NKG2A receptor are not alloreactive. Because the specificity of KIR for their ligands is broad and each individual carries several KIRs, it is likely that in most cases all NK cells of a given person express at least one KIR that is specific for a self-HLA class I allele. Thus in autologous settings, NK cells kill only aberrant cells that have lost HLA class I expression. By contrast, NK cells can kill allogeneic cells that do not express HLA class I alleles recognized by their KIR. Thus, by knowing the KIR repertoire of a given transplant recipient and the HLA type of the donor, it would theoretically be possible to predict the likelihood of an NK-mediated alloreaction. Importantly, it appears that alloreactive NK cells undergo proliferation on exposure to the stimulatory cells and therefore can preferentially expand in the presence of allogeneic tissue. NK cells also express activating receptors that are responsible for their lytic activity. Although the identity of the ligands for these receptors has not been identified, it is possible that they are expressed primarily by activated or proliferating cells. It is therefore possible that during the inflammatory process induced in allogeneic conditions, normal cells can become activated by cytokines and express ligands, which are responsible for NK activation in the absence of HLA class I molecules reactive with the inhibitory receptors.[93] The relevance of KIR in transplantation has been well studied in the context of haploidentical hematopoietic transplantation. In this case, several combinations are possible: NK cells from the graft express KIRs that do not interact with the donor's HLA (graft-versus-host alloreactivity). It seems that the presence of graft-versus-host reactive NK cells associated with incompatibilities between donor and recipient (especially HLA-Cw families) has favorable effects on the outcome of acute myeloid leukemia.[98] Alternatively, a good match may be present between graft NK and host HLA as well as between host NK and graft HLA. In such a case, no alloreactivity occurs. Finally, the graft's HLA type may be unsuitable for the host's NK repertoire, and the host's reactivity may lead to graft rejection. Alloreactive grafted NK cells seem to prevent GVHD while inducing GVN.[93]

Like HLA, KIR genes are polymorphic, and their variability is clustered in positions likely to affect the overall structure of the molecule. The relevance of KIR gene polymorphism in the outcome of bone marrow transplantation (BMT) is unclear. It appears that the risk for GVHD is highest in the context of unrelated BMT when the recipient KIR genotype is included in the donor KIR genotype.[99] These results show that compatibility between KIR genotypes themselves may influence the outcome of BMT.

The minor histocompatibility antigens (mHags) are represented by polymorphic molecules whose peptides containing variant sequences are presented by HLA alleles. They have been shown to be targets of cytotoxic T cells, which can lyse leukemia cells.[98,100] In addition, some mHags are selectively expressed by neoplastic cells.[101] At present, little is known about the identity of mHag epitopes in the context of various HLA types and their significance in the development of GVHD and GVN.

Cytokines are another large family of molecules associated with antigen recognition, graft rejection, and GVHD. Their polymorphism is becoming an important area of investigation in the context of transplantation, autoimmunity, and cancer.[102] Polymorphic sites reside in regulatory regions so that genetic variants are associated with high or low production of a given cytokine rather than differences in its function. A Web site compiles information about cytokine polymorphism (www.bris.ac.uk/Depts/PathAndMicro/services/GAI/cytokine4.htm). Although no consensus has been achieved yet, several studies have shown associations between various cytokine genotypes and propensity toward disease and transplant outcome. These studies have been summarized elsewhere.[92,103] A strong association was recently noted between a low interleukin-10 producer genotype and a tendency to develop melanoma and prostate cancer.[104,105]

HLA NOMENCLATURE

The history of the HLA system nomenclature was summarized by Sir Walter Bodmer who, together with Ruggero Ceppellini, was primarily involved in its development.[106] It began as HL-A, for *human leukocyte locus A.* With the recognition that HLA molecules are encoded by more than one locus, the A came to stand for *antigen* and a locus designation was added after HLA (i.e., HLA-A, -B, -C, -D, etc.).[2] From then on, the World Health Organization has updated on a quarterly basis. The most recent update was assigned in January 2012, as seen in Table 114-2.[4] At present two systems are used. An immunologically defined nomenclature is based on the identification of HLA antigens on the surface of leukocytes. Therefore HLA phenotypes described by immunologic methods are conventionally called *HLA antigens.*[107] The second system is based on the molecular identification of nucleotide sequences in genomic deoxyribonucleic acid (DNA), and results are conventionally referred to as *HLA alleles.*

Table 114-2 Name of Genes in the HLA Region Considered by the WHO Nomenclature Committee

Name	Previous Equivalents	Molecular Characteristics	No. of Alleles January (2012)
HLA-A	–	Class I α-chain	1757
HLA-B	–	Class I α-chain	2338
HLA-C	–	Class I α-chain	1304
HLA-E	E, "6.2"	Associated with class I 6.2-kBa Hind III fragment	10
HLA-F	F, "5.4"	Associated with class I 5.4-kBa Hind III fragment	22
HLA-G	G, "6.0"	Associated with class I 6.0-kBa Hind III fragment	47
HLA-H	H, AR, "12.4", HLA-54	Pseudogene association with class I 5.4-kBa Hind III fragment	12
HLA-J	cda 12, HLA-59	Pseudogene association with class I 5.9-kBa Hind III fragment	9
HLA-K	HLA-70	Pseudogene association with class I 7.0-kBa Hind III fragment	6
HLA-L	HLA-92	Pseudogene association with class I 9.2-kBa Hind III fragment	5
HLA-X	–	Class I gene fragment	0
HLA-DRA	DRα	DR α-chain	7
HLA-DRB1	DRβI, DR1B	DR β_1 determining specificity for DR1, DR2, DR3, etc.	1052
HLA-DRB2	DRβII2	Pseudogene with DRβ-like sequence	1
HLA-DRB3	DRβIII, DR3B	DR β3 determining DR52, Dw24, w25, -26 specificity	57
HLA-DRB4	DRβIV, DR4B	DR β4 determining DR53 specificity	15
HLA-DRB5	DRβV, DR5B	DR β5 determining DR52, Dw24, w25, -26 specificity	19
HLA-DRB6	DRBX, DRBσ	Pseudogene found in DR1, DR2, and DR10 haplotypes	3
HLA-DRB7	DRBψ1	Pseudogene found in DR4, DR7, and DR9 haplotypes	2
HLA-DRB8	DRBψ2	Pseudogene found in DR4, DR7, and DR9 haplotypes	1
HLA-DRB9	M 4.2 β exon	Pseudogene isolated fragment	1
HLA-DQA1	DQα1, DQ1A	DQ α-chain as expressed	47
HLA-DQB1	DQβ1, DQ1B	DQ β-chain as expressed	162
HLA-DOA	DNA, DZα, DOα	DO α-chain	8
HLA-DOB	DOβ	DO β-chain	9
HLA-DMA	RING 6	DM α-chain	4
HLA-DMB	RING 7	DM β-chain	13
HLA-DPA1	DPα1, DP1A	DP α-chain as expressed	33
HLA-DPB1	DPβ1, DP1B	DQ β-chain as expressed	152
TAP1	ABCB2, RING4	ABC (ATP-binding cassette) transporter	12
TAP2	ABCB3, RING 11	ABC (ATP-binding cassette) transporter	12
MICA	PERB 11.1	Class I chain–related gene	80
MICB	PERB 11.2	Class I chain–related gene 18	33

Data from Marsh SGE, Albert AD, Bodmer WF, et al: Nomeclature for factors of the HLA system, 2010. *Tissue Antigens* 75:291, 2010.
ATP, Adenosine triphosphate; *HLA,* human leukocyte antigen; *WHO,* World Health Organization.

Because molecular typing has higher resolution, it has gained increasing popularity.

IMMUNOLOGICALLY DEFINED HLA NOMENCLATURE

Immunologically defined nomenclature follows this rule: HLA separated by a hyphen from a capital letter identifying the locus encoding distinct HLA class I (-A, -B, -C) or class II (-DR, -DQ, -DP) antigens. The letter is followed by a number that identifies a serologic family of alleles sharing epitopes recognized by alloantibodies or alloreactive cytotoxic T cells. With improved understanding of the molecular genetics of the HLA region, various appendages have been removed from the HLA nomenclature. For instance, the letter *w* was used to indicate a provisional assignment, and this has been discontinued, but it is occasionally added to HLA-C antigen nomenclature to distinguish it from complement genes; DP and DW also maintained this letter to reinforce the dependency of their immune identification predominantly through cellular techniques. Finally, HLA-Bw4 and -Bw6 retain the *w* to emphasize that the public epitopes are shared by several HLA-B and some HLA-Antigens. More recently, a bridge between immunologic and molecular nomenclature has been proposed whereby HLA antigens that encompass a single gene product can be assigned a two-digit numeric extension corresponding to the molecular nomenclature for that allele.[108]

SEQUENCE-DEFINED ALLELIC NOMENCLATURE

The 10th International Histocompatibility Workshop recommended in 1987 a sequence-based nomenclature[108a] to describe alleles not

distinguishable by immunologic methods. Since then, the number of HLA alleles has rapidly increased. As of January 2012, a total of 7130 alleles for HLA exist. This is a drastic increase from the original numbers established in 2003. Other designations are summarized in Table 114-2. HLA designates molecules belonging to the human MHC followed by the locus (-A, -B, etc). Alleles are then identified after an asterisk (*). Each HLA allele name has a unique number corresponding to up to four sets of digits separated by colons. The length of the allele designation is dependant on the sequence of the allele and that of its nearest relative. All alleles receive at least a four digit name, which corresponds to the first two sets of digits, longer names are only assigned when necessary. The digits before the first colon describe the type, which often corresponds to the serological antigen carried by an allotype. The next set of digits are used to list the subtypes, numbers being assigned in the order in which DNA sequences have been determined. Alleles whose numbers differ in the two sets of digits must differ in one or more nucleotide substitutions that change the amino acid sequence of the encoded protein. Alleles that differ only by synonymous nucleotide substitutions (also called silent or non-coding substitutions) within the coding sequence are distinguished by the use of the third set of digits. Alleles that only differ by sequence polymorphisms in the introns or in the 5′ or 3′ untranslated regions that flank the exons and introns are distinguished by the use of the fourth set of digits.[108b] A four-digit number is used in which the first two digits refer to the original serologic family (e.g., HLA-A2 serologically would be HLA-A*02). Often numbers are missing because an original assignment was revoked (e.g., this is why there is no HLA-A*24:01). When silent mutations are identified (variation in nucleotide sequence that does not translate into changes in amino acid sequence), the name of the allele remains identical, but another two digits are added to designate a variant that has no functional significance. New sequences are submitted to European Molecular Biology Laboratory (EMBL; www.ebi.ac.uk/Submissions/index.html), GenBank (www.ncbi.nlm.nih.gov/Genbank/index.html), or DNA Data Bank of Japan (DDBJ; http://www.ddbj.nig.ac.jp/submission-e.html).

Requirements for new allele naming were described by Marsh et al.[4] The World Health Organization committee also made recommendations about naming alleles with aberrant expression such as HLA-G isoforms and KIR. Some alleles are identifiable at the genomic level but are not translated into protein (pseudogenes). These are indicated by the addition of an *N* (for null) following the numerical designation of the allele. Mutations inducing a reduction of expression are marked by *L* (low expression). An *S* denotes alleles expressed as soluble secreted molecules, such as HLA-B*44:02:01:02S characterized by an intronic variant that disallows the expression of the transmembrane domain of the HLA molecule and is therefore only in soluble form. Differential splicing of HLA-G leads to production of membrane-bound and soluble forms, which are respectively denoted by a lowercase *m* or *s* before HLA. Limited cytoplasmic expression is denoted by *C* and aberrant expression by *A.* Finally, KIR polymorphism will be classified by a new system that is in preparation.[4,97,109] A nomenclature system for cytokine polymorphism has not yet been developed.[110]

HLA TYPING IN CLINICAL HEMATOLOGY AND DETERMINATION OF COMPATIBILITY HLA TYPING

Originally HLA typing was done primarily in support of transplantation or transfusion needs with the purpose of identifying histocompatibility through the best match between donor and recipient. Allosensitization of recipients previously exposed to heterologous cell products is tested by identifying alloreactive antibodies in serum, and crossmatch procedures are performed to grade compatibility of candidate donor-recipient pairs. In addition, HLA testing has been applied to identify links between a given disease and the genetic makeup of its carriers.[111] Strong associations are exemplified by birdshot uveitis (a disease occurring exclusively in HLA-A29 individuals),[112] type 1 diabetes and other autoimmune diseases,[113-115] or long-term survival of HIV-infected individuals.[55] These studies evaluated the role that genetic background may have contributed over environmental factors.[111,116] HLA associations are thought to be caused by the differential ability of distinct alleles to present immunogenic epitopes[112,113] or by the close linkage to the HLA class III region where potent immunomodulators such as tumor necrosis factor-α are located.[117] It has also been suggested that HLA associations may be predictors of immune responsiveness of cancer to immune therapy.[60] However, such associations have remained quite difficult to reproduce.[118] HLA typing is requested for enrollment of patients into and interpretation of immunization protocols,[24] because specific HLA-epitope combinations require high-resolution typing.[22,119]

Serologic testing takes advantage of fetomaternal sensitization. In mammals, the progeny carries a full haplotype of paternal origin, and pregnant women may develop antibodies against the paternal haplotype. Maternal serum samples are collected at term and characterized by testing their ability to kill HLA-bearing repository cell lines of known phenotype in the presence of complement (complement-dependent cytotoxicity [CDC]).[120] Then CDC is used for HLA typing by exposing circulating cells expressing HLA class I (most cells) and class II (predominantly B cells) antigens from the individual (to be typed to previously characterized sera or monoclonal antibodies).[121] Conversely, already typed repository cell lines are used in CDC to identify alloantibodies in sera of sensitized individuals. The fraction of cell lines killed by the sera roughly grades the intensity of allosensitization or panel reactive antibody (PRA) reactivity. Some antibodies activate complement and kill with poor efficiency, known as the *cytotoxicity-negative absorption-positive (CYNAP) phenomenon.*[122] As judged by cytotoxicity testing, CYNAP may underestimate allosensitization. By modifying CDC with the addition of antihuman antibodies suitable for complement activation, CYNAP can be circumvented (augmented CDC). In this case, however, relatively innocuous antibodies can cause overestimation of clinically relevant allosensitization.[123] Other methods identify alloantibodies, including immobilization of HLA molecules on solid surface to capture soluble antibodies[124-126] and flow cytometry using a spectrum of microbeads loaded with known HLA alleles.[127,128] An interlaboratory comparison of serum screening for HLA-antibody determination suggested that enzyme-linked immunosorbent assay and flow cytometry yield higher PRA activity values compared with CDC or augmented CDC.[125] However, the study suggested a lack of consistency among participant laboratories, leaving unsolved the question of which method most accurately defines clinically relevant allosensitization, and a panel of various methods may be most informative.[72]

Complement-dependent cytotoxicity is declining in interest in the United States because most laboratories are switching to easier-to-handle and higher-resolution molecular methods. However, immunologic methods remain valuable to characterize functional aspects of HLA because molecular methods cannot define whether an HLA allele is expressed nor, at least until recently,[129] grade allosensitization. Thus it is likely that immunologic methods will continue to complement molecular methods in the future.[129]

The usefulness of conventional serologic typing has been limited by the availability of allele-specific sera. Most importantly, because antibodies identify structural differences on the surface of HLA molecules, variants caused by nucleotide polymorphism in nonexposed areas such as the peptide-binding groove of the HLA heavy chain are not detectable. However, these differences are of functional significance because they determine the specificity and affinity of peptide binding[130,131] and T-cell recognition of self and allogeneic target cells.[23,132] DNA-based typing directly determines the sequence,[133] and its resolution is limited only by the number of allele-specific probes used to identify an ever-growing number of alleles (see www.anthonynolan.com/HIG/index.htm). Various polymerase chain reaction (PCR)-based methods have been described, among which sequence-specific primer[133,134] and sequence-specific oligonucleotide probe[135,136]–based methods are the most universally used. The rich nature of HLA has led to proportionally increasing complexity of the assays used to cover all possible alleles. As a consequence, accurate HLA typing for donor and recipient matching in transplantation has

become increasingly complex and burdensome. In addition, because of the important role that HLA molecules play in antigen presentation and the stringency of the relationship between epitope and associated HLA allele, high-resolution typing is increasingly requested for appropriate enrollment of patients into immunization protocols aimed at the enhancement of T-cell responses.[137] Therefore high-resolution HLA typing is increasingly in demand in clinical and experimental settings.

Although oligonucleotide-based methods could theoretically discriminate any known polymorphic site, they have two major limitations. First, they require a specific PCR reaction for each allele investigated. Because each individual has only two alleles for each locus, a disproportionately large number of PCR reactions must be performed to cover all possible polymorphisms to identify the two borne by the individual tested. Because both methods are based on specific interactions with known oligonucleotide sequences unique to a particular allele, they cannot identify unknown polymorphisms unless the variation occurs within the region spanned by one of the oligonucleotides used in the assay. Because of these limitations, interest is growing for definitive typing methods that yield conclusive information about the identity of the alleles typed. The most comprehensive method is sequence-based typing. Unfortunately, its use has been limited by the cost of equipment and reagents and by the high level of expertise and time required for the interpretation of each typing. More recently, high-throughput, robotic, sequence-based typing has been developed that allows sequencing of hundreds of genomic fragments each day.[138-140] However, even sequence-based typing has some technical limitations. Some combinations of HLA class I and class II alleles result in ambiguous allele combinations that require additional testing for resolution.[141] Finally, new methods based on high-density array technology are being developed that may allow extensive typing of known and unknown polymorphisms on microchips.[142,143]

High-resolution methods yield high-resolution information of an individual's HLA type. However, the wealth of information is counterbalanced by increased difficulty in identifying suitable HLA alleles during donor-recipient pairing or accrual into immunization protocols restricted to specific HLA-epitope combinations. Thus at present clinicians are faced with the daunting task of applying high-resolution typing results of unclear relevance to clinical settings.[144]

TESTING FOR ALLOSENSITIZATION AND DETERMINATION OF COMPATIBLE RECIPIENT-DONOR PAIRS

Any cell-containing product transfused or transplanted between different individuals should be compatible in an ideal situation. Yet, in most cases, histocompatibility is not prospectively sought. Thus patients with multiple exposures to blood products often become reactive to various antigens, including HLA. Transplant candidates often develop prior alloreactivity following transfusion of platelet concentrates contaminated with leukocytes, even though the incidence of allosensitization is much less because of leukodepletion of blood products. Alloreactivity must be documented before transplantation, because alloreactive patients can still undergo transplantation, provided that the donor has no mismatched HLA antigens reacting with the patient's antibodies. Patients who have received repeated platelet transfusions may become allosensitized and consequently refractory to further transfusions unless HLA-compatible platelets are used. Obviously the best compatibility consists of identical matching. It is often impossible to identify a perfectly matched unrelated donor, particularly in the case of rare HLA types. Thus other strategies are adopted to identify the best possible match or compatible mismatch. Selection of unrelated donor-recipient pairs is carried out through typing with serologic, cellular, and molecular methods.[145] The chances of identifying compatible donors based on full or partial HLA matching have become increasingly low with the increasing resolution of the typing methods.[144] To broaden compatibility, matching criteria of donor-recipient pairs are based on shared public epitopes assigned to cross-reactive groups (CREGs)[146] or shared amino acid polymorphisms defined through sequence information (Table 114-3).[147] The preexistence of alloantibodies restricts the identification of compatible donors even further. Highly sensitized recipients with PRA activity exceeding 85% of tested specificities (generally between 30 and 60) represent a particularly challenging group.[148] An alternative approach to the exclusion of alloreactive determinants is the inclusion of acceptable antigen mismatches expressed in a panel of cells that give negative reactions with the recipient sera,[149] which extends the repertoire of possible donors. All these are fundamental tools for the identification of nonrelated, not fully matched donor-recipient pairs. Unfortunately, even these compromises often fail to identify a suitable match.

Duquesnoy[148] recently described a molecularly based algorithm to identify histocompatible pairs called HLAMatchmaker. This method focuses on the structural basis of HLA class I polymorphism so that compatible HLA mismatches can be identified without extensive serum screening. This algorithm is based on the principle that short amino acid sequences (triplets) characterizing polymorphic sites of the HLA molecules are critical components of allosensitizing epitopes. Such amino acids reside in the α-helices and β-loops of the heavy chain. Because each HLA molecule expresses a characteristic string of these determinants, it is possible to characterize each molecule according to the linear sequence of amino acid triplets present on its surface. Based on the reasonable assumption that none of the triplets present in the HLA repertoire of the recipient is self-immunogenic, it is possible through a process of electronic recombination to identify donors with HLA alleles different from the recipient's but containing exclusively shared triplets. These HLA alleles will be compatible, because they do not contain any epitope absent in the recipient.

In theory, a large number of triplets could occur if polymorphisms were randomly distributed. However, most HLA molecules span conserved domains, and only a total of 142 different polymorphic triplets designate serologically defined HLA-A, -B, and -C antigens.[148] Triplet polymorphism can occur in 30 locations on HLA-A, 27 in HLA-B, and 19 in HLA-C chains. Because the HLAMatchmaker algorithm includes interlocus comparison, it is possible to accumulate the information into a single database. Among the 142 polymorphic triplets, 29 are polymorphic for one class I locus but monomorphic for another class I locus. Such polymorphic triplets cannot be immunogenic because they are always present on the patient's own HLA antigens, whereas the remaining 113 triplets have immunogenic potential. With this algorithm, it is possible to significantly broaden the number of molecularly matched HLA alleles and significantly increase the chances of identifying a compatible donor, particularly in those cases in which the recipient has a rare HLA phenotype. In addition, HLAMatchmaker considers triplets that are present in the panel cells that give negative reactions with the recipient's serum. These negative panel cells can be expected to share antigens with the patient's, but other HLA antigens may be present and contain mismatched triplets apparently not immunogenic for that patient. Such triplets are therefore acceptable and can be added to the algorithm for the identification of possible donors. Thus HLAMatchmaker assesses HLA compatibility at a molecular level by determining whether or not a triplet in a given position of a mismatched HLA antigen is also found in the same position in any of the recipient's own HLA-A, HLA-B, and HLA-C molecules. A shared triplet in the same position on a mismatched HLA antigen cannot elicit a specific antibody response in that patient. This hypothesis needs future testing, because this strategy might represent a revolutionary tool for the identification of potential donors. Preliminary verification of the algorithm in a series of high-PRA renal patients suggested that this is a proper strategy at least in highly sensitized renal transplantation candidates waiting for unrelated donors.[150] HLAMatchmaker is also effective at selecting an optimal HLA-typed platelet component for alloimmunized thrombocytopenic patients.[151]

A new version of HLAMatchmaker considers so-called eplets and is based on the structural definitions of functional epitopes on well-characterized protein antigens that have been complexed with anti-

Table 114-3 Population Frequencies of Major Cross Reactive or Determinants Present on HLA-A and -B Gene Products

Major Cross-Reactive Group	Public Epitope	Associated Private Epitopes	Approximate Epitope Frequency (%)*
1C	1p	A1, 3, 9 (23, 24), 11, 29, 30, 31, 36, 80	79

body.[152] Eplets represent amino acid residue configurations within a 3- to 3.5-Å radius of each polymorphic residue on the HLA molecular surface. Many eplets correspond to triplets, but eplets represents a more complete repertoire of structurally defined epitopes.

THE HLA MOLECULES AS ANTIGENS AND HLA ALLOIMMUNIZATION

By no means are HLA molecules antigenic in physiologic condition (with the exception of maternofetal alloimmunization). However, because of their high density on the surface of cells, they can become highly immunogenic in the nonphysiologic event in which cells from different individuals are exposed to another person's immune system. The mechanism or mechanisms leading to allosensitization are believed to follow two pathways. The first pathway mimics the one followed during most immune reactions in which antigen is up taken by antigen-presenting cells and presented to autologous lymphocytes (indirect pathway). In this case the donor's HLA molecules are processed into peptides through the exogenous pathway of antigen presentation and presented to autologous T cells as linear peptides.[153,154] This pathway is believed to be responsible for the development of alloantibodies as well as T-helper cell responses, but its role in the development of cytotoxic T-cell responses remains unclear. Because this pathway depends on the presentation of donor HLA molecules by recipient HLA alleles, it may explain why the humoral response to HLA class I allodeterminants correlates with the HLA phenotype of the responder.[155] The indirect pathway of HLA allorecognition has been associated with allograft rejection.[156] Because the function of HLA molecules is to present antigenic determinants to T cells, it could be easily envisioned how minor changes in their structure could be misinterpreted as antigenic epitopes. Intact HLA molecules residing on the surface of donor cells are a perfect target for T cell–mediated allorecognition (direct pathway) either through the direct cytotoxic effect of T cells against target cells or by the activation of helper T cells, through HLA class II engagement, which leads to stimulation of antibody-mediated immune responses.[157]

Humoral responses mediated most frequently by IgM are predominant in the sensitization to infrequent allogeneic exposure, because they require smaller amounts of antigenic material. T-cell responses become more manifest in the context of transplantation in which the persistence of the allogeneic stimulus allows the expansion and sustenance of alloreactive cytotoxic T cells. Antibodies and TCR have different requirements for their engagement, which means epitopes recognized by T cells and antibodies are different. Antibodies require interaction with a small structure, including a limited number of amino acids; thus any sequence combination on the surface of an HLA allele not present in the individual exposed to the alloreaction may represent an epitope. T cells have much lower binding affinity for their ligand and require a complete interaction with the peptide as well as the α– and β–helices of the HLA class I heavy chain.[11] Although several B-cell epitopes recognized by antibodies can be identified in a given HLA molecule, generally the whole HLA molecule is necessary for T cell–dependent allorecognition. Definition and topographic mapping of epitopes defined by serologic or cellular methods has revealed distinct regions of hypervariability in the α-1 and α-2 domains of the class I heavy chains and in the α-1 and β-1 domains of class II molecules.[158] Two types of antibody-defined epitopes can be identified according to their frequency among HLA alleles. Private epitopes are almost but not totally unique for a single serologically defined HLA antigen and are used for typing. These epitopes are generally shared by all molecular alleles present in that given family, and fine differences among alleles within a general family cannot be distinguished by antibodies. Public epitopes are more widely distributed and cluster distinct serologic families into groups. These epitopes bear an immunodominant character. Immune sera that identify public epitopes have been considered predictive of major CREGs with the idea that alloreactivity among patients belonging to the same CREG may be less likely (see Table 114-3). The predictive value of CREGs in transplant outcome or platelet transfusion results, however, remains to be demonstrated.

Not all subjects who have been exposed to alloantigens develop alloantibodies, and in fact exposure to low doses of donor-specific HLA antigens through donor transfusion may have a beneficial effect on graft survival.[159] Obviously, the degree of compatibility in the context of allosensitization may vary according to the degree of mismatch between donor and recipient. In addition, alloantibodies are one aspect of alloreaction that does not take into account cellular responses. These have been more difficult to document, although they are likely to play an important role in the context of acute transplant rejection. Several hypotheses have been discussed about the reason or reasons for the capriciousness of allosensitization,

including the presence of regulatory immune responses or cytokine-mediated immunosuppression. Currently the mechanism modulating the quality and quantity of alloimmunity remains elusive, and different aspects of this algorithm are discussed ad hoc in this chapter, with particular attention to molecularly defined algorithms for the prediction of histocompatibility.[129,148,160,161]

Clearly, HLA matching is beneficial in patients undergoing renal transplantation. An analysis of more than 150,000 recipients receiving transplants in different centers participating in the Collaborative Transplant Study showed that a complete mismatch (6 HLA-A+B+DR) had a 17% lower survival expectation than no mismatch (P <0.0001).[162] Matching was particularly beneficial in patients with highly reactive preformed alloantibodies. The same study suggested that high-resolution matching based on molecular typing improved graft survival. Similar results were observed in cases of cardiac transplantation in which HLA matching yielded significantly better results (P <0.0001). This is particularly important because donor hearts are currently not allocated according to HLA match in most centers. In cases of liver transplantation, HLA matching was not beneficial.[163]

Donor-specific hyporesponsiveness has been particularly well documented in the context of renal allotransplantation and may limit the need for immunosuppression. A recent randomized study suggested that pretransplant donor transfusions improved the survival of cadaver kidney grafts in patients receiving modern immunosuppressive regimens, but the mechanism remains unclear.[164,165] Although most centers currently do not implement deliberate blood transfusions, the usefulness of this approach needs to be investigated further.

Approximately 5% to 10% of platelet transfusions are given to patients who have been previously exposed to HLA class I–expressing heterologous cells and are reactive to HLA antigens. Such patients are refractory to random-donor platelets and must be given HLA-matched or semimatched plateletpheresis components.[41-44] However, a provision of HLA-matched platelets does not always improve platelet recovery and survival. Possibly, the ineffective platelet transfusion is in part caused by unrecognized HLA mismatches between the donor and recipient resulting from the low-resolution methods used for typing, and higher resolution methods have been advocated. It is currently controversial whether or not molecularly based HLA typing confers an advantage over serologic typing, and this principle was recently questioned in the context of hematopoietic cell transplantation.[166,167]

HLA AS A FUNCTIONAL MEDIATOR OF GRAFT-VERSUS-HOST DISEASE AND/OR GRAFT-VERSUS-NEOPLASIA EFFECT

Allogeneic or syngeneic bone marrow transplantation is used predominately for the treatment of hematologic malignancies[168-170] and other hematologic disorders such as aplastic anemia,[171] thalassemia,[172] or myelodysplastic syndrome.[173] This strategy can induce long-term disease-free survival in chronic myelogenous leukemia patients.[168,169] The objective of bone marrow transplantation in cases of malignancy is to cure the patient by eradication of the neoplastic cells with myeloablative chemotherapy followed by restoration of hematopoiesis through the transplantation of normal hematopoietic stem cells derived from HLA-compatible normal donors. This strategy is characterized by the insurgence of an immune reaction toward the host's normal cells (GVHD),[174-176] which is often associated and preferentially targets neoplastic cells (GVN effect).[177-184] Both the GVHD and the GVN effect occur in the presence of a full HLA match; thus the HLA molecules are not targets of allosensitization themselves but present polymorphic molecules expressed by the recipient's cells recognized by the grafted immune cells.

GRAFT-VERSUS-HOST DISEASE

GVHD represents the alloimmune reaction of donor lymphocytes against normal cells of the recipient. GVHD occurs predominantly in association with hematopoietic progenitor cell transplantation (HPCT) compared to other types of transplants because the hematopoietic transplant is enriched of immune cells. Myeloablative therapy is generally administered before transplantation and, as a consequence, in most cases prevents graft rejection. GVHD is a major complication of HPCT, and a fine balance between GVHD and graft rejection is maintained by modulating the level of posttransplantation immunosuppression.[184] In addition, other major disturbances associated with HPCT, such as overwhelming infection, leukemia, or tumor relapse, and other regimen-related morbidities are strongly influenced by the treatment of GVHD. With the advent of nonmyeloablative HPCT for the treatment of nonhematologic diseases such as solid tumors, GVHD has reached a predominant role because of its close association with GVN effect.

T-cell depletion has been advocated for the prevention of GVHD by decreasing the probability of cellular and humoral alloresponses.[185,186] This strategy decreases the occurrence of GVHD but is associated with an increased risk for graft rejection and tumor or leukemia relapse.[184] In fact, Weiden et al[187] observed that survivors of severe acute GVHD had a significantly lower incidence of tumor relapse compared with patients who did not experience GVHD. This association appeared mandatory, and it was believed that the beneficial GVN reaction was inseparable from GVHD.

The risk for GVHD increases with genetic distancing between donor and recipient. Thus recipients of transplants from HLA-identical twins have a lesser chance of developing GVHD than recipients of transplants from HLA-unrelated donors and from donors with only a partial HLA match.[188,189] Interestingly, however, although the genetic closeness between donor and recipient appears to decrease the risk for GVHD, it also decreases the therapeutic benefit, with increased chances of tumor relapse.

GRAFT-VERSUS-NEOPLASIA EFFECT

It was originally observed that a beneficial collateral effect of GVHD was the rejection of neoplastic cells by the donor immune system in the context of hematologic malignancies (graft-versus-leukemia effect).[177] It was rapidly recognized that the graft-versus-leukemia effect could play a powerful therapeutic role in the treatment of refractory malignant disorders, including some solid tumors (graft-versus-tumor effect).[181] Because the biology and clinical principles underlining the two effects are likely similar, for simplicity, in this chapter we coin a unifying term: *graft-versus-neoplasia effect.* Indeed, there is a perception that the GVN reaction is the most potent form of tumor immunotherapy currently in clinical use. Its mechanism of action is still poorly understood. T cells definitely play a fundamental role in the initiation and maintenance of the alloreaction toward neoplastic cells.[190] A sevenfold increase in the chance of relapse was noted in patients with chronic myelogenous leukemia who received a T cell–depleted BMT as compared with a subset of patients who had received a T cell–repleted BMT but did not develop GVHD.[185,186] This result suggested that GVHD is a biologic entity different from GVN effect. In addition, on leukemia relapse, administration of donor lymphocyte infusion could reinduce clinical remission.[191] Finally, leukemia-specific $CD8^+$ T cells have been identified in circulating lymphocytes at the time of leukemia regression.[192] NK cells play an additional role in mediating this phenomenon, and clinical data suggest that mismatch of NK receptor and ligands during allogeneic BMT can be used to enhance the GVN effect.[93,193] Appreciation of the GVN effect has led to the development of nonmyeloablative stem cell transplants designed to immunosuppress the host to a level sufficient to permit engraftment of the donor immune cells to generate GVN without inducing the serious complications associated with myeloablation.[184] The GVN effect has gained popularity in the last decade to the point that allogeneic-based immunotherapeutic approaches have been advocated for several nonhematologic malignancies.[184] The rationale is largely based on the assumption that the immune cell repertoire capable of recognizing cancer cells in the allogeneic context is broader than in the autologous system. Donor

T cells can target not only tumor-specific antigens but also allelic variants of these antigens; mHag; and, in the case of HLA-mismatched transplants, HLA antigens disparate from the donor expressed by the tumor cells.[194-196] Although there are several theories about how the GVN effect occurs, it remains unclear why allo-T cells have a better chance of targeting tumor cells in an allogeneic context as compared with the natural insurgence of antitumor immunity described for several solid tumors.

HLA AND T CELL–DIRECTED IMMUNIZATION

The last decade has witnessed remarkable progress in the identification and mapping of T-cell epitopes for various infectious diseases and cancer. In particular, progress was made in mapping HLA-associated epitopes for HIV, cytomegalovirus, and Epstein-Barr virus.[197-200] In addition, the molecular identification of tumor-associated antigens has yielded a large number of epitopes that could be used to immunize against neoplasia.[201] A comprehensive discussion of these topics is beyond the scope of this chapter, but we address a few points framing the relevance of HLA in the context of T cell–directed immunization.

The identification of T-cell epitopes led to two major areas of clinical investigation. The first is active-specific immunization to prevent or treat ongoing infections or cancer. The second is the harvest and in vitro expansion of immunization-induced T cells for adoptive transfer. In general, active immunization has proved successful in inducing epitope-specific T cells easily detectable among circulating lymphocytes.[119,202-204] However, often the immunization-induced enhancement of T-cell function is not associated with clinical improvement. Although the reason for the clinical ineffectiveness of immunization-induced T cells is unclear, it has been postulated that they may be quantitatively[203] or qualitatively[205] inadequate for eradicating disease. Therefore a second strategy is being pursued whereby the number of antigen-specific T cells is amplified in vitro for autologous or donor-derived adoptive transfer. This second strategy has met some promising success in the context of ganciclovir-resistant cytomegalovirus infection,[206] Epstein-Barr virus–induced posttransplantation lymphoproliferative disorders,[207] and metastatic melanoma.[208]

Whether delivered as a primary form of therapy or to prime in vivo T cells for further ex vivo expansion, epitope-specific vaccination encounters the major limitation of a stringent requirement for HLA allelic association. Although superfamilies of HLA alleles may share epitopes,[14,15] in practical terms, clinically relevant HLA-epitope associations are restricted to few peptide-allele combinations for a given protein.[22] Patients considered for enrollment in immunization protocols are best served by high-resolution HLA typing to exclude subtypes with unproven immunogenic potential for a given epitope. To bypass the stringent HLA requirements demanded by epitope-specific vaccination, whole-antigen delivery is suggested. This is based on the assumption that the epitope repertoire of a protein can be adjusted to distinct HLA phenotypes by a cellular process of self-selection naturally coupling peptides to HLA according to binding affinity. Although theoretically indisputable, in practice the truth of this assumption depends on the efficiency with which individual molecules are processed and presented in association with distinct HLA alleles. Even in these settings, high-resolution typing is desirable because it allows accurate interpretation of immunization results by allowing a comparison between the detailed genetic makeup of the individual receiving the vaccine and his or her antigen-specific immune response. It is likely that in the future HLA laboratories will receive increasing demands for high-resolution, definitive typing for appropriate patient enrollment and for subsequent interpretation of immune responses.

MONITORING IMMUNE RESPONSES WITH TETRAMERIC HLA-PEPTIDE COMPLEXES

A growing understanding of the molecular immunology of T-cell interactions with HLA/epitope complexes in the context of infectious disease, virally induced malignancies, and spontaneous tumors as well as interest in their treatment with T cell–directed vaccines has generated more attention to the issue of using accurate methods to quantify ex vivo the extent of antigen-specific immune responses.[209] The most commonly used assays available for the enumeration of antigen-specific T cells include tHLA; intracellular fluorescence-activated cell sorter staining for cytokine expression on cognate stimulation; detection of cytokine release by enzyme-linked immunospot assay; and quantitative real-time PCR, recently reviewed by Keilholz et al.[210] tHLAs are complexes of four HLA molecules combined with a specific peptide and bound to a fluorochrome (Fig. 114-6). These complexes bind to complementary TCR and identify antigen-specific T

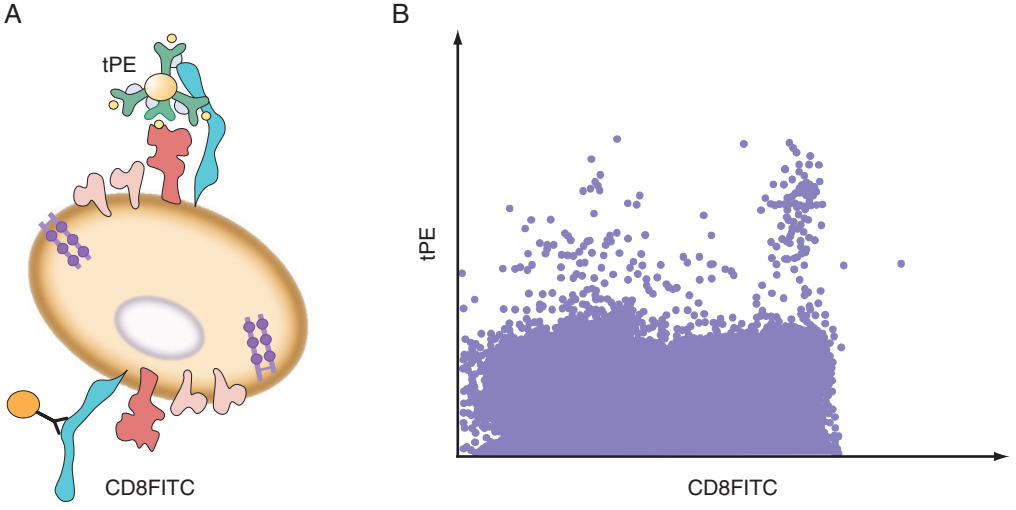

Figure 114-6 SCHEMATIC REPRESENTATION OF THE MECHANISM OF BINDING OF TETRAMERIC PEPTIDE/HUMAN LEUKOCYTE ANTIGEN COMPLEXES (THLA) TO ANTIGEN-SPECIFIC T CELLS. **A,** Binding of tHLA to T-cell receptor. The tHLA consists of four HLA/peptide complexes identical to the ones recognized by the T cell on the surface of live cells. Each HLA molecule is modified to contain one biotin molecule that serves as a bridge for binding to tetravalent streptavidin molecules fluorescently labeled. **B,** Actual fluorescence-activated cell sorter (FACS) analysis result of $CD8^+$, tHLA-positive T cells. *(Modified from Monsurro V, Nargosen D: Immunotracking of specific cancer vaccine CD8 lymphocytes,* ASHI Q *26:100, 2003.)*

cells,[211] measuring cellular responses against specific epitopes with sensitivity as low as 1 in 5000 $CD8^+$ T cells. To synthesize tHLA molecules, soluble HLA heavy chains containing a biotinylation site and recombinant β_2-microglobulin are synthesized and purified. They are then refolded in the presence of the specific epitope, and the monomer is isolated by gel filtration and is biotinylated. Fluorescent streptavidin is added to induce tetramerization. An aliquot of tetramers is added to the peripheral blood mononuclear cells together with other antibodies for a more detailed characterization of antigen-specific T cells.[205] Analysis is performed using a flow cytometer. Because of the specificity of vaccines, the patient's HLA type and specific peptide must be identified and synthesized to provide the adequate tetramer. Pentameric HLA/peptide complexes have recently become available and in some laboratories have replaced the use of tHLA.

Analysis of tHLA offers many potential advantages over other T-cell assays. This method is quantitative and enables an estimation of the avidity between TCR and peptide-loaded HLA class I molecules. tHLA staining does not kill the labeled cells, allowing sorting of subpopulations by flow cytometry for additional analysis or expansion for adoptive transfer. With tHLA specific T cells can be analyzed from blood samples without the prerequisite of in vitro culture, and all specific cytotoxic T lymphocytes are detected, regardless of their functional status.[203,205,212]

HLA SUMMARY

The relevance of HLA in clinical pathology has broadened from its role as a predictor of allosensitization to a mediator of GVHD and GVN. The understanding of action mechanisms in various nonclassic HLA genes as well as KIR has opened a new field. The study examining the function of the innate immune response in the context of transplantation and other immunopathologies is a result of this. Together with HLA, immunogenetics is rapidly growing, driven by the realization that polymorphism is the hallmark of human immunopathology as its spans mHag, KIR, cytokines, and their receptors. Each of these is interwoven in an intricate array of interdependent functions that cannot be discounted. Modern methods should be able to adopt high-throughput systems for the parallel assessment of all these variables when addressing the genetic makeup of an individual in correlation with the natural or therapeutic history of his or her disease. The comparison of donor and recipient protein profiling and cytokine polymorphism may offer insights into the rejection mechanism when matched-donor grafts are used. Finally, the increased use of T cell–directed immunization is driving renewed interest in high-resolution typing of HLA molecules to allow a more accurate interpretation of clinical and immunologic results.

HUMAN NEUTROPHIL ANTIGENS AND THEIR CLINICAL SIGNIFICANCE

Lalezari et al described the first granulocyte antigens. These antigens were designated *N* for neutrophil. Each antigen system was described alphabetically, and each allele was described numerically in order of discovery. They identified NA1 in 1966 and its allele, NA2, in 1972.[213,214] In 1971, Lalezari et al[215] described another granulocyte antigen, NB1. Reports of several other granulocyte antigens followed.

A new nomenclature was established in 1998 by the International Society of Blood Transfusion Working Party (Table 114-4).[216] In this nomenclature, antigen systems are referred to as *human neutrophil antigens,* or HNA. The antigen systems—that is, the polymorphic forms of the immunogenic proteins—are indicated by integers, and specific antigens within each system are designated alphabetically by date of publication. Alleles of the coding genes are named according to the Guidelines for Human Gene Nomenclature. Neutrophil antigens NA1 and NA2 became HNA-1a and HNA-1b in the new nomenclature, and NB1 became HNA-2a.

Table 114-4 International Society of Blood Transfusion Nomenclature

Antigen System	Antigens	Location	Former Name	Alleles
HNA-1	HNA-1a	FcγRIIIb	NA1	FCGR3B*1
	HNA-1b	FcγRIIIb	NA2	FCGR3B*2
	HNA-1c	FcγRIIIb	SH	FCGR3B*3
HNA-2	HNA-2a	CD177 (NB1 gp)	NB1	CD177*1
HNA-3	HNA-3a	70-95 kDa gp	5b	Not defined
HNA-4	HNA-4a	CD11b (CR3)	Mart(a)	CD11B*1
HNA-5	HNA-5a	CD11a (LFA-1)	Ond(a)	CD11A*1

CR3, C3bi receptor; *gp,* glycoprotein; *HNA,* human neutrophil antigen; *LFA-1,* leukocyte function–associated antigen-1.

Neutrophil antigens were first characterized using clinically important alloantibodies and autoantibodies. Most often, neutrophil-specific alloantibodies are directed toward antigens in the HNA-1 or HNA-2 systems. The availability of many different alloantibodies and monoclonal antibodies to HNA-1 and HNA-2 antigens has allowed the characterization of these antigen systems. In addition, three other antigen systems have been partially characterized, HNA-3, HNA-4, and HNA-5. The serology, biochemistry, molecular biology, and clinical significance of these antigens are reviewed here.

THE HNA-1 ANTIGEN SYSTEM

Expression of HNA-1 Antigens

HNA-1 antigens are expressed only on neutrophils. HNA-1 antigens are located on the low-affinity Fc-γ receptor IIIb (FcγRIIIb), CD16.[217-220] FcγRIIIb, HNA-1a, HNA-1b, and HNA-1c antigens are expressed on all segmented neutrophils, approximately one-half of neutrophilic metamyelocytes, and approximately 10% of neutrophilic myelocytes.[221] Neutrophil expression of FcγRIIIb and HNA-1 antigens are diminished by the treatment of neutrophils with stimulants such as complement component C5a and chemotaxin F-met-leu-phe or granulocyte colony-stimulating factor (G-CSF). Soluble Fc γ RIIIb is present in plasma, and it has the same HNA-1 polymorphisms found on neutrophils. Fc γ RIIIb released from granulocytes is the source of the soluble Fc γ RIIIb and HNA-1 antigens.[222]

Biochemistry

Fc γ RIIIb is a glycoprotein with 233 amino acids and is glycosylphosphatidylinositol (GPI) anchored.[217-220] Its molecular weight is 50 to 80 kDa, and the glycoprotein has *N*-linked carbohydrate side chains. HNA-1a form of Fc γ RIIIb is 50 to 65 kDa, the HNA-1b form of Fc γ RIIIb is 65 to 80 kDa, and the heterozygous form is 50 to 80 kDa. Differences in *N*-glycosylation account for the differences in molecular mass.

Molecular Biology

Fc γ RIIIb and the HNA-1 antigens are encoded by the FCGR3B gene located on chromosome 1q23-24 within a cluster of two families of Fc γ R genes, FCGR2 and FCGR3. The FCGR3 family is made up of FCGR3A and FCGR3B. FCGR3B is highly homologous to FCGR3A, which encodes Fc γ RIIIa. Only four nucleotides differ between FCGR3B and FCGR3A (Table 114-5). The most important difference between the two genes is a C to T change at 733 in

Table 114-5 Nucleotide Differences Among the Genes Encoding the HNA-1a, HNA-1b, and HNA-1c Antigens of Fcγ RIIIb Base Pair Position

HNA, Human neutrophil antigen.
*N-Glycosylation site.
†Stop codon.
Note: Differences among genes are in bold.

FCGR3B that creates a stop codon. As a result, FCGR3A has 21 more amino acids than FCGR3B, and FCGR3A is a transmembrane rather than GPI-anchored glycoprotein. Fc γ RIIIa is not recognized by antibodies specific to HNA-1 antigens, but the similarities between FCGR3A and FCGR3B complicate genotyping of HNA-1 alleles.

HNA-1a, -1b, and -1c Polymorphisms

The neutrophil-specific HNA-1 antigen system is made up of the three alleles, HNA-1a, -1b, and -1c.[223] The antigens are also known as NA1, NA2, and SH (see Table 114-4). The gene frequencies of the three alleles vary widely among different racial groups. Among whites, the frequency of the gene encoding HNA-1a, FCGR3B*1, is between 0.30 and 0.37, and the frequency of the gene encoding HNA-1b, FCGR3B*2, is from 0.63 to 0.70.[224-228] In Japanese and Chinese populations, the FCGR3B*1 gene frequency is from 0.60 to 0.66, and the FCGR3B*2 gene frequency is from 0.30 to 0.33.[217,219-221,224,226-228] The gene frequency of the gene encoding HNA-1c, FCGR3B*3, also varies among racial groups. FCGR3B*3 is expressed by neutrophils in 4% to 5% of whites and 25% to 38% of African Americans.[229]

The FCGR3B*1 gene differs from the FCGR3B*2 gene by only five nucleotides in the coding region, at positions 141, 147, 227, 277, and 349 (see Table 114-5).[217-220] Four of the nucleotide changes result in changes in amino acid sequence between the HNA-1a and HNA-1b forms of the glycoprotein. The fifth polymorphism at 147 is silent. The glycosylation pattern of the protein differs between the two antigens because of two nucleotide changes at bases 227 and 277. HNA-1b form has six *N*-linked glycosylation sites, and HNA-1a form has four glycosylation sites.

The gene encoding the HNA-1c form of Fc γ RIIIb, FCGR3B*3, is identical to FCGR3B*2 except for a C to A substitution at nucleotide 266 resulting in an alanine to aspartate change at amino acid 78 of Fc γ RIIIb (see Table 114-5).[223] In many cases, FCGR3B*3 exists on the same chromosome with a second or duplicate FCGR3B gene.[223,230] One group has found that in Danish people, FCGR3B*3 always exists as a duplicate gene in association with FCGR3B*1.[231] However, in other populations duplicate FCGR3B*3 genes were associated with both FCGR3B*1 and FCGR3B*2.

Several other sequence variations in FCGR3B have been described.[226] These chimeric alleles have single-base substitutions involving one of the five single-nucleotide polymorphisms that distinguish FCGR3B*1 and FCGR3B*2. FCGR3B alleles that more closely resembled FCGR3B*2 were found more often in African Americans than in whites or Japanese.[226]

FC γ RIIIB Deficiency

Blood cells from patients with paroxysmal nocturnal hemoglobinuria lack the GPI-linked glycoproteins, and their granulocytes express reduced amounts of Fc γ RIIIb and the HNA-1 antigens.[220] Genetic deficiencies of granulocyte Fc γ RIIIb and HNA-1 antigens have also been reported. With inherited deficiency of Fc γ RIIIb, the FCGR3B gene is deleted along with an adjacent gene, FCGR2C.[225,232] Among white subjects the incidence of individuals homozygous for FCGR3B deletion is about 0.1%.[233,234] However, among Africans and African Americans the incidence is much higher; in one study, 3 of 126 Africans were found to be FCGR3B deficient,[229] and, in another, 1 of 53 was found to be FCGR3B deficient.[226]

Function of HNA-1 Antigens

The low-affinity Fc-γ receptors link humoral immunity to cellular immune function; specifically, Fc γ Rs on effector cells recognize cytotoxic IgG molecules and immune complexes containing IgG molecules. Polymorphisms in Fc γ RIIIb affect neutrophil function. Neutrophils that are homozygous for HNA-1b have a lower affinity for IgG3 than granulocytes homozygous for HNA-1a.[235] Neutrophils from people who are homozygous for HNA-1b phagocytize erythrocytes sensitized with IgG1 and IgG3 anti-Rh monoclonal antibodies and bacteria opsonized with IgG1 at a lower level than granulocytes homozygous for HNA-1a.[236,237]

Clinical Relevance of FC γ RIIIB Deficiency

Despite the important role of Fc γ RIIIb in neutrophil function, deletion of the entire Fc γ RIIIB gene does not cause major clinical problems, and most people with Fc γ RIIIb deficiency are healthy. However, too few patients have been studied to identify a slight increase in susceptibility to infection or autoimmune disease due to Fc γ RIIIb deficiency. In a study of 21 people with Fc γ RIIIb deficiency, 2 were found to have autoimmune thyroiditis and 4 had multiple episodes of bacterial infections.[232] Other smaller studies and case reports have found that despite their Fc γ RIIIb deficiency, all individuals, except for the one person with systemic lupus erythematosus, were healthy, had no circulating immune complexes, and showed no increased susceptibility to infections.

FCGR3B Polymorphisms and Disease Associations

Several studies suggest that FCGR3B polymorphisms affect the incidence and outcomes of some autoimmune and inflammatory diseases, but the results seem contradictory. Children with chronic immune thrombocytopenia purpura are more likely to be FCGR3B*1 homozygous than control subjects,[238] but Spanish patients with systemic lupus erythematosus are more likely to be FCGR3B*2 homozygous.[239] Myasthenia gravis is more severe in FCGR3B*1 homozygous patients,[240] but multiple sclerosis is more benign in FCGR3B*1 homozygous patients.[241] Patients with chronic granulomatous disease who are FCGR3B*1 homozygous are less likely to develop major gastrointestinal or genitourinary tract infectious complications than heterozygous and FCGR3B*2 homozygous chronic granulomatous patients.[242] Because FCGR3B is clustered with FCGR3A and

FCGR3B on chromosome 1q22, it is possible that some of these findings may be caused in part by linkage disequilibrium among Fc receptors.

THE HNA-2 ANTIGEN SYSTEM

HNA-2 system has one well-described allele, HNA-2a. It was previously known as NB1.[215] Monoclonal antibodies specific to HNA-2a have been clustered as CD177.

Expression of HNA-2a

HNA-2a is neutrophil-specific antigen. It is expressed only on neutrophils, neutrophilic metamyelocytes, and myelocytes.[221,243] HNA-2a is unique in that it is expressed on subpopulations of neutrophils. The mean size of the HNA-2a–positive subpopulation of neutrophils is 45% to 65%.[244-246] The expression of HNA-2a is greater on neutrophils from women than men.[246,247] The size of the HNA-2a–positive subpopulation of neutrophils from women is approximately 60%, compared with approximately 50% for men. The expression of HNA-2a falls with age in women but remains constant in men.[246] Neutrophil expression of HNA-2a is greater in pregnant women than in healthy female blood donors.[247] The surface expression of HNA-2a is slightly upregulated by treatment with the chemotactic peptide F-met-leu-phe.[244] The administration of G-CSF to healthy subjects for several days increases the proportion of neutrophils expressing HNA-2a to near 90%.[248]

NB1 Glycoprotein Biochemistry

The glycoprotein carrying HNA-2a, NB1 glycoprotein, is located on neutrophil plasma membranes and secondary granules[244,249] and is linked to the plasma membrane via a GPI anchor.[244] Although some GPI-anchored proteins are shed by F-met-leu-phe–treated neutrophils, NB1 glycoprotein is not, nor is soluble NB1 glycoprotein present in plasma.[244] The molecular weight of NB1 glycoprotein is 58 to 64 kDa, and it contains *N*-linked carbohydrate side chains.[244,249]

Molecular Biology

The gene encoding NB1 glycoprotein, CD177, is located on chromosome 19q13.31, and its coding region consists of 1311 bp that code for a protein of 416 and a signal peptide of 21 amino acids.[250,251] The predicted protein has two cysteine-rich domains, three potential *N*-linked glycosylation sites, and a potential ω-site for attachment of the GPI anchor.[250] This gene belongs to the Ly-6 snake toxin superfamily. Other genes in this family include urokinase-type plasminogen activator receptor (uPAR) (CD87) and decay-accelerating factor (CD59).

Two different groups sequenced CD177 independently. One group sequenced it as the gene encoding HNA-2a and called the gene NB1,[250] and the other group sequenced it as a gene overexpressed in granulocytes from people with polycythemia rubra vera and called the gene PRV-1.[252] The NB1 and PRV-1 alleles differ at only 4 bp.[250] Bettinotti et al[253] used Human Genomic Project databases to characterize the structure of the PRV-1 and NB1 genes. They described the intron and exon structure of NB1, but they found only one gene homologous to both PRV-1 and NB1, suggesting that they are alleles of the same gene that they called CD177. In addition, they found a pseudogene homologous to exons 4 through 9 of CD177.[253]

Polymorphisms

HNA-2a is expressed on neutrophils by approximately 97% of whites, 95% of African Americans, and 89% to 99% of Japanese.[246,254,255] HNA-2a has been reported to have an allele, NB2; but the product of this gene cannot be reliably identified with alloantisera, and no monoclonal antibody specific for NB2 has been identified.[256]

HNA-2a negative neutrophil phenotype is caused by a CD177 transcription defect.[257] HNA-2a genes from two women with HNA-2a–negative neutrophils who produced HNA-2a–specific alloantibodies have been studied, and CD177 complementary DNA (cDNA) sequences were present in both women.[257] However, all neutrophil CD177 messenger ribonucleic acid (mRNA) contained accessory sequences that were considered to be introns. HNA-2a–negative phenotype was the result of different off-frame insertions at the RNA level, resulting in NB1 gp deficiency in neutrophils.[257]

Role of NB1 Glycoprotein in Neutrophil Function

The role of CD177 in neutrophil function is unknown. In some studies HNA-2a may have a role in the adhesion of neutrophils to endothelial cells.[258] Upregulation of HNA-2a after F-met-leu-phe stimulation, HNA-2a internalization on antibody cross-linking, and activation of the respiratory burst after binding of HNA-2a antibodies to HNA-2a–bearing neutrophils suggest a possible role as receptor molecule.[259]

Clinical Relevance of HNA-2 Antigens

The rare women who produce HNA-2a–specific alloantibodies and who lack NB1 glycoprotein are healthy. The expression of HNA-2a is reduced on neutrophils from people with paroxysmal nocturnal hemoglobinuria and chronic myelogenous leukemia.[243] It is unknown whether the lack of expression of HNA-2a on neutrophils from patients with paroxysmal nocturnal hemoglobinuria or chronic myelogenous leukemia has any clinical significance. CD177 mRNA is overexpressed by neutrophils from patients with polycythemia rubra vera and essential thrombocytosis.[252,260] Some groups are using quantitative real-time PCR to measure neutrophil CD177 mRNA levels to assist with the diagnosis of polycythemia rubra vera and essential thrombocytosis. Patients with essential thrombocytosis and increased CD177 mRNA levels have been reported to have increased risk for thrombocytosis and bleeding.[261] Patients with polycythemia rubra vera and essential thrombocytosis have been found to have gain of function mutations in the gene encoding Janus kinase-2 (JAK2)[262-266] and the increased expression of CD177 mRNA in neutrophils from these patients may be secondary to the JAK2 mutation.

HNA-3 ANTIGEN SYSTEM

HNA-3 antigen system has one antigen, HNA-3a, that was previously known as 5b. HNA-3a is expressed by neutrophils, lymphocytes, platelets, endothelial cells, kidney, spleen, and placental cells. HNA-3a has a gene frequency of 0.66 and is located on a 70- to 95-kDa neutrophil glycoprotein.[267] The gene encoding HNA-3a has not yet been cloned, and the nature and function of the 70- to 95-kDa glycoprotein is unknown. Although the biologic role for this system has not been established, several cases of transfusion-related acute lung injury (TRALI) have been associated with transfusion of plasma containing anti-5b.[268,269]

HNA-4 AND HNA-5 ANTIGEN SYSTEMS

HNA-4 and HNA-5 antigens are located in the β_2-integrins. Each antigen system contains only a single antigen, HNA-4a and HNA-5a, respectively. HNA-4a antigen was previously known as Mart(a). HNA-4a was defined by an antibody in the sera of three nontransfused multiparous blood donors. The antigen was shown to have

autosomal dominant inheritance and has a phenotype frequency of 99.1% in white subjects. HNA-4a has been located on the αM chain (CD11b) of the C3bi receptor (CR3) and is caused by a single nucleotide substitution of G to A at position 302.[270] The substitution would be predicted to result in an arginine to histidine polymorphism at amino acid 61. The significance of the antibody is unknown, and none of the infants of the three multiparous women with anti–HNA-4a showed evidence of neonatal alloimmune neutropenia.

A second polymorphism of the β_2-integrins, HNA-5a, was first described as Ond(a). A chronically transfused man with aplastic anemia became alloimmunized to HNA-5a. HNA-5a was found to be expressed on the αL integrin unit, leukocyte function–associated antigen-1 (LFA-1) (CD11a), and is caused by a G to C single nucleotide substitution at position 2446. This change predicts an amino acid change of arginine to threonine at amino acid 766.[270]

CLINICAL SIGNIFICANCE OF ANTIBODIES TO NEUTROPHIL ANTIGENS

Alloimmune Neonatal Neutropenia

During pregnancy, mothers can become alloimmunized to neutrophil antigens. Maternal IgG directed to neutrophils can cross the placenta and destroy the neonate's neutrophils. Maternal alloimmunization to neutrophil antigens can occur in utero and affect the first child. Most neonates experience isolated neutropenia, but the cytopenias are self-limiting and resolve as the antibody is cleared. The alloimmunized mothers produce and carry the antibodies; but the antibodies do not react with the mother's blood cells or tissues, and they have normal neutrophil counts. Antibodies to neutrophil-specific antigens HNA-1a, HNA-1b, and HNA-2a most commonly cause neonatal alloimmune neutropenia (Table 114-6).[267,271] Antibodies to HNA-1c and HNA-3a rarely cause alloimmune neonatal neutropenia. Mothers with FcγRIIIb deficiency have produced FcγRIIIb-specific antibodies that caused neonatal neutropenia.[234,267,271]

Newborns with alloimmune neutropenia are usually asymptomatic. Most often, the neutropenia is detected in the first week of life when the neonate becomes febrile or develops an infection and a neutrophil count is done. Typically the counts are 0.100 to 0.200×10^9/L. Some neonates have normal neutrophil counts the first day of life, but they become neutropenic on their second day.[271] White blood cell count, platelet count, and hemoglobin level are usually normal; but eosinophilia or monocytosis may be present. If a bone marrow biopsy is performed, it often shows normal numbers of erythroid progenitors and megakaryocytes with hyperplasia of myeloid progenitors.

The clinical course is quite variable. An occasional infant is asymptomatic, but almost all affected children have an infection. The most common infections are umbilicus infections, skin infections, abscesses, and respiratory tract infections. Less commonly, infants experience otitis media, urinary tract infections, and gastroenteritis. Serious infections such as sepsis, pneumonia, and meningitis can occur. The duration of the neutropenia may be as short as a few days or as long as 28 weeks.[271] The mean duration of neutropenia is about 11 weeks.[271]

For an asymptomatic child, no immediate treatment may be required. Prompt and aggressive antibiotic treatment of children with fevers or other signs of infections is indicated. Intravenous immunoglobulin has a limited role in the treatment of neonatal alloimmune neutropenia. Approximately half the patients treated have a transient increase in count lasting only a few days. The use of G-CSF to treat alloimmune neutropenia has also had mixed results. The administration of G-CSF elevates the neutrophil count in some but not all neonates.[271]

Table 114-6 Specificities of Antibodies in Alloimmune Neonatal Neutropenia

Antigen	*N* = 18[211,271]	*N* = 48[253,267]
HNA-1a	28%	10%
HNA-1b	22%	8%
FcγRIIIb	0%	8%
HNA-2a	11%	2%
HNA-3a	0%	2%
Unknown	0%	15%
HLA class I[251,271]	11%	54%
Negative	28%	38%

HLA, Human leukocyte antigen; *HNA,* human neutrophil antigen.

AUTOIMMUNE NEUTROPENIA OF CHILDHOOD

Autoimmune neutropenia has been well described in children.[272-275] Typically the onset of the autoimmune neutropenia of children begins at 8 months of age, but children between 1 and 36 months of age can be affected. Most studies found that neutrophil counts recover spontaneously by the age of 5 years, with a median of 13 to 20 months of neutropenia.[272-275]

In most cases, children presented with severe neutropenia, having neutrophil counts less than 0.5×10^9/L. Monocytosis has been reported to occur in up to 38% of patients. Results of bone marrow biopsies in affected patients usually show normal to hypercellular marrow with a decreased number of mature granulocytes. Febrile episodes and infections, including bacterial skin infections, otitis media, respiratory tract infections, and urinary tract infections, are common. Life-threatening complications are rare.

Antibodies to neutrophils can be detected in up to 98% of affected patients. If an antibody specificity is identified, the antibodies are almost always specific to epitopes located on FcγRIIIb. The antibodies are directed to HNA-1a in 10% to 46% of patients, to HNA-1b in 2% to 3% of patients, and rarely to FcγRIIIb epitopes expressed by granulocytes from all donors.[273,274]

Autoimmune neutropenia has been treated with corticosteroids, intravenous immunoglobulin, and G-CSF. Approximately half the patients responded to intravenous immunoglobulin, but neutrophil counts remained elevated for only 1 week.[273] Almost all the patients responded to G-CSF and 75% to corticosteroids, and neutrophil counts remained elevated as long as the drugs were given.

TRANSFUSION REACTIONS

Antibodies to neutrophil and HLA antigens can cause febrile nonhemolytic transfusion reactions and TRALI. Before the widespread transfusion of leukocyte-reduced blood components, approximately 0.5% of transfusions were associated with febrile nonhemolytic transfusion reactions, and leukocyte antibodies are a common cause of these reactions. These febrile reactions are caused by the interaction of leukocyte antibodies in the transfusion recipient with leukocytes contained in the transfused blood components. These reactions can be prevented by the use of components that have been filtered to remove leukocytes.

A more serious type of transfusion reaction associated with leukocyte antibodies is the acute noncardiac pulmonary edema, or TRALI. This entity is characterized by acute respiratory distress that usually occurs within 4 hours after a transfusion. These reactions are characterized by dyspnea, hypoxia, and bilateral pulmonary infiltrates on chest radiograph without cardiomegaly or pulmonary vascular congestion. The mortality rate associated with TRALI is approximately 5%.[276] Of patients with TRALI, 80% have rapid resolution of pulmonary infiltrates and return of arterial blood gas values to normal within 96 hours after the initial respiratory insult. However, pulmonary infiltrates have persisted for at least 7 days after the transfusion reaction in 17% of TRALI patients.

TRALI has been associated with both neutrophil and HLA antibodies. Antibodies reported in these reactions include HNA-1a, HNA-1b, HNA-2a, HNA-3a, and HLA class I and II antibodies. Most of these cases involve the passive transfusion of the offending antibody in donor plasma, as contrasted with the reactivity of the recipient's antibody with donor leukocytes to cause febrile nonhemolytic reactions. Retrospective studies involving antibodies to HNA-3a have implicated blood components from single donors with anti-HNA-3a in several TRALI cases.[269]

GRANULOCYTE TRANSFUSIONS

Granulocyte transfusion recipients sometimes produce antibodies specific to HNA-1a, HNA-1b, and HNA-2a. The transfusion of granulocytes to patients with these antibodies can result in febrile transfusion reactions and pulmonary transfusion reactions.[277] HPCT recipients who produce HNA-2a antibodies as a result of granulocyte transfusions have experienced marrow graft failure.[278]

NEUTROPHIL ANTIGENS SUMMARY

Two neutrophil antigen systems, HNA-1 and HNA-2, have been well described, and three others, HNA-3, HNA-4, and HNA-5, have been described in part. HNA-1 antigens are located on FcγRIIIb, and antibodies to these antigens are frequently implicated in autoimmune and alloimmune neutropenia. HNA-2a is located on NB1 glycoprotein, and antibodies to HNA-2a are found in patients with alloimmune and autoimmune neutropenia. The gene expressing this protein is overexpressed by neutrophils in patients with polycythemia rubra vera. Antibodies to HNA-3a are rare; but relative to other neutrophil antibodies, may be more frequently associated with cases of TRALI. The significance, if any, of HNA-4a and HNA-5a antibodies is uncertain.

CHAPTER 115

PRINCIPLES OF NEUTROPHIL (GRANULOCYTE) TRANSFUSIONS

Ronald G. Strauss

Current cytapheresis technology permits collection of large numbers of several types of blood leukocytes (e.g., neutrophils, hematopoietic progenitors/stem cells, and lymphocytes) from either healthy donors (allogeneic use) or patients (autologous use)—who often are stimulated with recombinant cytokines such as granulocyte colony-stimulating factor (G-CSF)—to be used for transfusion and transplantation or for further processing (e.g., ex vivo expansion and genetic manipulation). Polymorphonuclear neutrophils (PMNs) are granulocytic leukocytes that are collected from healthy donors and issued as a standard blood component (granulocytes, pheresis). This chapter analyzes the use of neutrophil (i.e., granulocyte) transfusions (GTX) as an adjunct to antimicrobial drugs in the treatment and prevention of progressive infections in patients with severe neutropenia or PMN dysfunction.

Life-threatening infections with bacteria, yeast, and fungus continue to be a consequence of severe neutropenia ($<0.5 \times 10^9$/L blood PMNs), most commonly occurring after intense chemotherapy of hematopoietic progenitor cell (HPC) transplantation, and disorders of PMN dysfunction such as chronic granulomatous disease. The most frequent clinical situation today is neutropenic fever and infection following intense chemotherapy or HPC transplantation given to treat hematologic malignancies. Neutropenic infections cause considerable morbidity, occasionally are fatal, and add considerable cost to the management of these patients. However, because of improved antifungal prophylaxis and therapy following HPC transplantation, severe fungal infections often occur after neutrophil engraftment (i.e., due more to longer-standing immunodeficiency), and neutrophil transfusions (GTX) of course are not warranted during this later time in the posttransplant period. Thus the number of patients with severe fungal infections, for whom GTX previously were considered, has decreased—further questioning the need in some physicians' opinions for GTX therapy.

Previous attempts to prevent infections in severely neutropenic patients by transfusing PMN concentrates (i.e., prophylactic GTX) achieved only questionable success. Although rates of certain infections were significantly reduced by prophylactic GTX, many adverse effects, such as pulmonary infiltrates and cytomegalovirus infections, were reported, and GTX were expensive. Thus prophylactic GTX have gained little support over the years. Similarly, use of therapeutic GTX to resolve existing infections has not gained lasting acceptance, despite many reports documenting significant benefit. This lack of enthusiasm for GTX can be explained by the continuing development of new and very effective antimicrobial drugs to prevent and treat infections and by the availability of recombinant hematopoietic growth factors and peripheral blood hematopoietic progenitor cell (PBHPC) transfusions—both of which hasten patient recovery from myelotoxic therapy and thereby shorten the period of risk for neutropenic infections. The lack of familiarity of some oncology and transplant physicians with the markedly improved modern PMN concentrates available for transfusion today plus the lack of definitive clinical trials with modern GTX undoubtedly limit use of GTX.

Historically, PMN concentrates were collected for transfusion from unstimulated donors or those stimulated only with corticosteroids and contained woefully inadequate numbers of PMNs. Currently, very large numbers of PMNs can be collected from normal donors using G-CSF plus corticosteroid marrow stimulation followed by large-volume leukapheresis, during which several liters of donor blood are processed. In this chapter the historical and modern experiences with GTX are reviewed, and the current technology of PMN collection is discussed.

THERAPEUTIC GRANULOCYTE TRANSFUSIONS IN NEUTROPENIC PATIENTS' HISTORICAL EXPERIENCE

In the third edition of this book, 34 papers were reviewed that reported the therapeutic use of GTX—collected before the advent of G-CSF donor stimulation—in severely neutropenic patients ($<5 \times 10^9$/L blood PMNs). Data were tabulated (Table 115-1) according to the index infection that prompted GTX therapy. Patients were counted only once (e.g., patients with septicemia were listed only in the septicemia group, even if they had another infection, such as pneumonia). As an exception, all patients with invasive fungal infections were counted together because it was impossible to accurately separate sepsis, pneumonia, sinusitis, and so forth into distinct categories. All patients given GTX for a designated type of infection were enumerated in the "Treated" column. The treated patients, those for whom the actual course and mortality of the index infection could be clearly documented, were enumerated again in the "Evaluable" column. GTX therapy was considered successful if so stated by the authors. Combining data from multiple reports of varying experimental design admittedly is of limited value for drawing firm conclusions, and it was done simply to document the breadth of historical reported experience.

To obtain more definitive information regarding efficacy of historical GTX (i.e., collected without G-CSF), the seven controlled studies were analyzed in more detail.[1-7] In these seven studies, the response of infected neutropenic patients to treatment with GTX plus antibiotics (study group) was compared with that of comparable patients given antibiotics alone and evaluated concurrently (control group). The design, size, and results of these seven studies are presented in Tables 115-2 and 115-3. Three of the seven studies reported a significant overall benefit for GTX.[4-6] In two additional studies,[1,3] overall success was not demonstrated for GTX, but certain subgroups of patients were found to benefit significantly. Some measure of success for GTX was evident in five of the seven controlled studies. However, this success was counterbalanced by four studies that were negative in some respect—two totally[2,7] and two partially negative.[1,3]

An explanation of these inconsistent results is evident on critical analysis of the adequacy of GTX support (see Table 115-3). Patients in the three successful trials received relatively high doses of PMNs (generally $\geq 1.7 \times 10^{10}$/day).[4-6] Donors were selected to be erythrocyte AND leukocyte compatible. By contrast, the four controlled studies yielding negative results can legitimately be criticized. Two of the four studies with negative conclusions used PMNs collected by filtration leukapheresis for some patients.[1,3] It is now known that such PMNs are defective, and they are no longer transfused. In the negative studies using PMNs collected by centrifugation leukapheresis,[2,3,7] the dose was extremely low (0.41 to 0.56×10^{10} per concentrate). As another factor, investigators in two of the four negative studies[1,7] made no provision for the possibility of leukocyte alloimmunization, because donors were selected solely on the basis of erythrocyte

compatibility. Finally, control subjects responded reasonably well to antibiotics alone in three of the four negative studies,[1,3,7] suggesting that some patients fared so well with conventional treatment that they had no apparent need for additional therapeutic modalities.

These impressions from the seven controlled GTX trials have been analyzed by formal meta-analysis,[8] with conclusions that the dose of PMNs transfused and the survival rate of the nontransfused control subjects were primarily responsible for the differing success rates of the historical studies. In clinical settings in which the survival rate of nontransfused control subjects was low, study subjects benefited from receiving adequate doses of GTX—prompting the authors to suggest that severely neutropenic patients with life-threatening infections should be considered to receive GTX given in adequate doses.[8]

Table 115-1 Infectious Problems in Neutropenic Patients Treated With Historical Granulocyte Transfusions in 34 Studies

Type of Infection	Treated	Evaluable	Success Rate (%)
Bacterial septicemia	298	206	127/206 (62)
Sepsis organism unspecified	132	39	18/39 (46)
Invasive fungus and yeast	83	77	28/77 (36)
Pneumonia	120	11	7/11 (64)
Localized infections	143	47	39/47 (83)
Fever etiology unknown	184	85	64/85 (75)

MODERN EXPERIENCE

Bacterial, fungal, and yeast infections occur frequently in patients with severe neutropenia or PMN dysfunction, and when these infections fail to promptly respond to antimicrobial drugs, they pose a major challenge for which modern therapeutic GTX offer a possible answer. Recipients of HPC transplants—particularly marrow transplant patients—often become severely neutropenic and exhibit PMN dysfunction shortly after transplant. Importantly, they manifest defective cellular and humoral immunity for months after transplantation. Altered immunity is particularly profound when the HPC graft is T-lymphocyte depleted to diminish graft-versus-host disease. Hence all types of infection pose a threat, with fungal and yeast infections being major problems. In a series of 1186 marrow transplant patients, 10% developed a noncandidal fungal infection, with only 17% of infected patients surviving. When the marrow graft is depleted of T lymphocytes, the rate of infection is increased twofold to sevenfold above that occurring with standard bone marrow transplantation.

Data are insufficient to determine the proper role of GTX in treating fungal/yeast infections (which are of the greatest importance). Historical case reports, experimental studies in animals, and experience in treating patients with chronic granulomatous disease have supported the efficacy of GTX in fungal infections. In contrast, a large clinical study reported that GTX collected in the pre–G-CSF era were of no benefit in treating fungal and yeast infections in 87 bone marrow transplant patients, 50 of whom received GTX. Although this study was a retrospective review with several shortcomings that must be interpreted cautiously, as pointed out later, the poor response of invasive fungal infections in neutropenic patients to even modern GTX is supported by recent reports.

At this time, no randomized clinical trials of therapeutic GTX collected after G-CSF donor stimulation have been completed and reported to establish the efficacy or potential toxicity of modern GTX. One randomized controlled clinical trial of therapeutic GTX collected following G-CSF donor stimulation has been reported, but it was closed before completion with less than 50% of patients entered because of futility (i.e., poor enrollment).[9] Moreover, the design of the trial was less than ideal, because donors were stimulated only with G-CSF without combination with corticosteroids, resulting in relatively low PMN doses, and GTX were given only every other day, rather than daily. However, five case reports (Table 115-4) and six uncontrolled studies of multiple patients (Table 115-5) will be reviewed.[10-20]

Clarke et al[10] and Catalano et al[12] each reported single patients (see Table 115-4) with aplastic anemia undergoing HPC transplantation with fungus infections that responded favorably to strikingly different doses of PMNs. Similarly, Ozsahin et al[13] and Bielorai et al[14] each reported single patients (see Table 115-4) with chronic

Table 115-3 Design of Seven Controlled Studies Evaluating Historical Therapeutic Granulocyte Transfusions in Neutropenic Patients

Investigators	Randomized?	Collection Method	Dose ($\times 10^{10}$)	Schedule	HLA*	WBC*

Fortuny et al[2]	No	Centrifugation	0.4	Daily	No	Yes

HLA, Human leukocyte antigen; *WBC,* white blood cell.
*Donors selected to be compatible with recipient either by HLA typing (A and B loci matched, at least in part) or by leukocyte crossmatching.

Table 115-4 Case Reports of Modern Therapeutic Granulocyte Transfusions Using Neutrophils Collected From Granulocyte Colony-Stimulating Factor–Stimulated Donors in Neutropenic Patients

Investigators	PMNs × 10^{10} per Each GTX	Stimulation	Leukapheresis	Outcomes
Clarke et al[10]	5.3*	G-CSF 5-10 mcg/kg	Dextran 10 L processed	One patient with fungus recovered
Catalano et al[12]	1.9	G-CSF 300 mcg/dose	Not described	One patient with fungus recovered
Ozsahin et al[13]	3.1	G-CSF 5 mcg/kg	Hetastarch 5-7 L processed	One patient with fungus recovered
Bielorai et al[14]	7.0*	G-CSF 5 mcg/kg	Not described	One patient with fungus recovered
Bielorai et al[15]	4.8-6.8	Not described	Not described	One patient with vancomycin-resistant *Enterococcus* recovered

G-CSF, Granulocyte colony-stimulating factor; *GTX,* granulocyte transfusions; *PMN,* neutrophil.
*Assumptions made because PMN dose expressed × 10^{10} unclear in these reports. Dose calculated that would be given to a 70-kg recipient for Clarke et al and Bielorai et al.

Table 115-5 Groups of Neutropenic Patients Treated With Modern Therapeutic Granulocyte Transfusions Using Neutrophils Collected From Granulocyte Colony-Stimulating Factor–Stimulated Donors

Investigators	PMNs × 10^{10} per Each GTX	Stimulation	Leukapheresis	Outcomes
Hester et al[11]	4.1	G-CSF 5 mcg/kg	Pentastarch 7 L processed	60% (9 of 15) Success with fungus (11 patients) and yeast (4 patients)
Grigg et al[16]	5.9*	G-CSF 10 mcg/kg	Dextran 10 L processed	100% (3 of 3) Success with bacterial infection 0% (0 of 5) Success with progressive fungus 67% (2 of 3) Success with stable fungus
Peters et al[17]	3.5*	G-CSF 5 mcg/kg -or- Prednisolone	Hetastarch 6.4 L processed	82% (14 of 17) Success with bacterial infection 54% (7 of 13) Success with fungal infection
Price et al[18]	8.2	G-CSF 600 mcg/kg -plus- Dexamethasone 8 mg	Hetastarch 10 L processed	100% (4 of 4) Success with bacterial infection 0% (0 of 8) Success with invasive fungus 57% (4 of 7) Success with yeast infection
Lee et al[19]	5.1-10.6	G-CSF 5 mcg/kg -and/or- Dexamethasone 3 mg/m^2	Pentastarch 6-10 L processed	40% (10 of 25) Success with multiple-organism infections
Hubel et al[20]	4.6-8.1	G-CSF 600 mg/kg -with or without- Dexamethasone 8 mg	Hetastarch or pentastarch 10 L processed	55% (unrelated donor) Success with bacterial infection 75% (family donor) Success with bacterial infection 0% (unrelated donor) Success with yeast infection 40% (family donor) Success with yeast infection 15% (unrelated donor) Success with fungal infection 25% (family donor) Success with fungal infection

G-CSF, Granulocyte colony-stimulating factor; *GTX,* granulocyte transfusions; *PMN,* neutrophil.
*Assumptions made because PMN dose expressed × 10^{10} unclear in these reports. PMN dose calculated using values for range of leukocytes collected, percentage of collected cells being myeloid, and volume of units collected (Grigg et al). Dose calculated that would be given to a 70-kg recipient for Peters et al.

granulomatous disease and fungal infections that responded favorably to GTX during the transplantation period. Bielorai et al[15] reported a single patient with acute leukemia and sepsis with progressive, antibiotic-resistant bacteria whose infection cleared slowly with GTX. It is impossible, in these single reports of very complicated patients, to firmly ascribe the good outcome to the GTX.

Hester et al[11] transfused 15 patients with hematologic malignancies and infections (see Table 115-5). PMNs were collected from donors stimulated only with G-CSF and selected without regard for leukocyte compatibility. Although GTX were successful in most patients, it was not possible to distinguish responses of fungus versus yeast infections. Lee et al[19] transfused 25 patients with hematologic malignancies, many of whom were infected with multiple organisms. PMNs were collected from donors stimulated with G-CSF alone (66% of donors), G-CSF plus dexamethasone (25% of donors), or dexamethasone alone (8% of donors). Of patients with sepsis, 50% (2 of 4) responded favorably, and 38% (8 of 21) of patients with progressive localized infections responded favorably. Grigg et al[16] transfused 11 patients (see Table 115-5). Eight patients had hematologic malignancies and progressive infections—five of the eight undergoing progenitor cell transplantation and three receiving chemotherapy. Three additional patients who were undergoing progenitor cell transplantation had stable fungus infections. PMNs were collected from donors stimulated only with G-CSF and selected without regard for leukocyte compatibility. Success was excellent for bacterial and stable fungus infections but was quite poor for progressive fungus infections with organ dysfunction—a troubling pattern reported by others.[18]

Peters et al[17] transfused 30 patients (see Table 115-5) with hematologic disorders—18 undergoing HPC transplantation. PMNs were collected from donors stimulated with G-CSF or prednisolone and selected without regard for leukocyte compatibility. The exact PMN dose transfused is uncertain because values from 0.9×10^{10} to 14.4×10^{10} can be calculated from data reported, and it was impossible to

distinguish the success of GTX from G-CSF–stimulated versus prednisolone-stimulated donors. However, the outcome of bacterial infections appeared to be superior to that of fungus infections.

Price et al[18] transfused 19 patients (see Table 115-5) with hematologic malignancies, 16 who had received HPC transplants and 3 who were pretransplantation recipients. PMNs were collected from donors stimulated with G-CSF and dexamethasone. Although donors were selected without regard for leukocyte compatibility, recipients were documented not to exhibit evidence of leukocyte alloimmunization at study entry. Bacterial infections responded well, and yeast infections responded modestly. Despite very high PMN doses, success for invasive fungus infections was dismal.

Lee et al[19] transfused 25 patients with hematologic malignancies. Many were infected with multiple organisms. Donors were stimulated with G-CSF plus dexamethasone (25%), G-CSF alone (66%), or dexamethasone alone (8%). Of septic patients, 50% (2 of 4) responded favorably, and 38% (8 of 21) of patients with localized infections responded.

Hubel et al[20] expanded the study of Price et al[18] to a total of 74 patients (see Table 115-5) with HPC transplants. Controls were 74 historical patients not given GTX. Donors were either family members or unrelated individuals stimulated with G-CSF with or without dexamethasone. Comparative favorable responses varied with family versus unrelated donors but were approximately 70% for bacterial, 50% for yeast, and 20% for fungal/mold infections—values similar to the historical control patients not given GTX.

The report of Safdar et al[21] is not presented in Table 115-5 because many aspects of the patients and their infections are quite heterogeneous. The study was a case-control retrospective analysis of 491 cancer patients with candidemia—29 given GTX and 462 not. Donors were stimulated with G-CSF plus dexamethasone, and GTX were given either daily or on alternate days. Not all patients were evaluable, but unexpectedly only 35% of patients given GTX resolved their infections versus 67% of those not given GTX ($p < .001$). However, death ascribed to candidemia was almost identical: 48% in the GTX group and 45% in the control patients.

No firm conclusions can be drawn from these somewhat anecdotal and very heterogenous reports of modern therapeutic GTX for several reasons: (1) the only randomized control trial was not completed and was of very questionable scientific design, and in most other reports no concurrent control subjects were included (i.e., randomly assigned to receive no GTX or GTX from donors stimulated only with corticosteroids); (2) the number of patients reported was quite small; and (3) PMN collection methods and GTX transfusion schedules were variable, with a broad range of PMN doses transfused. On the basis of these preliminary findings—acknowledging the many shortcomings—bacterial infections appeared to respond well to modern GTX, and relatively mild fungus and yeast infections responded modestly well, whereas serious/invasive fungus infections with tissue damage resisted even the large doses of PMNs transfused with modern GTX.[16-18] The precise role of modern therapeutic GTX, collected from donors stimulated with G-CSF plus corticosteroids, in the management of infected, neutropenic, oncology/transplant patients awaits definition by well-designed randomized clinical trials.

EXPERIENCE IN INFANTS AND CHILDREN

Most patients with congenital disorders of PMN dysfunction have adequate numbers of blood PMNs, but they are susceptible to serious infections because their PMNs fail to kill pathogenic microorganisms. Patients with severe forms of PMN dysfunction are relatively rare, and no randomized clinical trials have been reported to establish the efficacy of therapeutic GTX in their management. Firm recommendations about the use of GTX to treat patients cannot be made. However, several patients with chronic granulomatous disease, complicated by progressive life-threatening fungal infections, have been reported to benefit. Because of the possibility of alloimmunization to leukocyte and red blood cell antigens plus the other risks of allogeneic transfusions, such as pulmonary reactions and transfusion-transmitted infections, therapeutic GTX are recommended only for progressive infections that cannot be controlled with antimicrobial drugs. Because of lifetime problems with infections, prophylactic GTX are impractical.

Neonates (infants within the first month of life) are another group of patients who may suffer life-threatening bacterial infections caused, at least in part, by PMN dysfunction and neutropenia. Neutropenia must be viewed differently in neonates than in older patients. In older infants and children, GTX are considered usually when the blood PMN count falls to less than 0.5×10^9/L. By contrast, because normal neonates exhibit a physiologic neutrophilia compared to normal PMN counts in older children and adults, absolute blood PMN counts as high as 3.0×10^9/L (i.e., relative neutropenia) might prompt consideration of GTX in neonates.[22] The mechanism of neutropenia cannot always be identified, but in some infants a marked decrease in the marrow PMN storage pool can be demonstrated. For example, storage pool neutrophils (metamyelocytes and segmented PMNs) account for 26% to 65% of all nucleated cells in normal marrow, but in some neonates with sepsis, this value will be less than 10% of nucleated marrow cells.

Six controlled trials have assessed the role of GTX in treating neonatal infections. Although four of the six found a significant benefit for GTX, the controlled studies, when assessed by meta-analysis, were insufficiently homogeneous to permit clear recommendations regarding the efficacy of GTX.[8] The varying dose of PMNs transfused was identified as the primary reason for disagreements in results among studies. When leukapheresis PMN concentrates with higher doses of PMNs were transfused, GTX were beneficial. When buffy coats with lower doses of PMNs were transfused, GTX were not beneficial.[8] The role of therapeutic GTX for neonatal infections is unclear at present and, because they are transfused only rarely at this time, they will not be discussed further. However, the possible roles of immunoglobulin and cytokine therapies for neonatal sepsis will be discussed later.

PROPHYLACTIC GRANULOCYTE TRANSFUSIONS IN NEUTROPENIC PATIENTS

Based on historical reports, prophylactic GTX were of marginal value. In 12 reports, benefits were few, whereas risks and expenses were substantial. However, some measure of success was found in 7 of 12 studies; the remaining 5 studies failed to show a benefit for prophylactic GTX. In none of these five negative studies were large numbers of PMNs obtained from matched donors and transfused daily. In a situation analogous to that for the negative therapeutic GTX trials, the failure of prophylactic GTX might be explained, at least in part, by inadequate transfusions (see box on Collection and Transfusion of Neutrophil Concentrates).

The role of modern prophylactic GTX (i.e., from G-CSF–stimulated donors) has not been established by definitive clinical trials. However, two factors suggest possible success: (1) because of the rapid recovery from myeloablation, hastened by peripheral blood HPC transplantation plus treatment of patients with recombinant growth factors such as G-CSF, the period of severe neutropenia may be as short as 1 week; and (2) this relatively brief period of severe neutropenia might literally be eliminated by transfusing large doses of PMNs collected from donors stimulated with G-CSF plus corticosteroids. A few studies have begun to explore this possibility (Table 115-6).

Bensinger et al[23] transfused seven allogeneic marrow recipients with PMNs collected from their HLA-identical or syngeneic marrow donors after G-CSF stimulation. Because donors experienced leukapheresis on consecutive days, collection techniques were quite variable in terms of quantities of hydroxyethyl starch infused and liters of donor blood processed—thus the number of PMNs collected varied from 0.3 to 14.4×10^{10}. Recipients received an average of 7.6 GTX while awaiting marrow recovery, and recipients were given 5 mcg/kg G-CSF daily to maintain a mean blood PMN count of

Table 115-6 Modern Prophylactic Granulocyte Transfusion Studies Using Neutrophils Collected From Granulocyte Colony-Stimulating Factor–Stimulated Donors in Hematopoietic Progenitor Cell Transplant Recipients

Investigator	PMNs × 10^{10} Per Each GTX	Stimulation	Leukapheresis	Outcomes
Bensinger et al[23]	4.2	G-CSF 3.5-6 mcg/kg	Variable	Not reported
Adkins et al[24]	4.1 (day 1) 5.1 (day 3) 6.1 (day 5)	G-CSF 5 mcg/kg × 5 Days posttransplant	Hetastarch 7 L processed Days 1, 3, and 5	60% (6 of 10) afebrile 40% (4 of 10) febrile 3 culture positive
Adkins et al[25]	5.6 (day 2) 7.0 (day 4) 8.5 (day 6) 9.9 (day 8)	G-CSF 10 mcg/kg	Hetastarch 7 L processed Days 2, 4, 6, and 8	Reduction of fever and antibiotics if no leukocyte antibodies

G-CSF, Granulocyte colony-stimulating factor; *GTX,* granulocyte transfusions; *PMN,* neutrophil.

Collection and Transfusion of Neutrophil Concentrates

To ensure adequate numbers and quality of polymorphonuclear neutrophils (PMNs) for transfusion, PMNs must be collected from stimulated donors by automated leukapheresis using an erythrocyte sedimenting agent, such as hydroxyethyl starch. A major limitation of granulocyte transfusion (GTX) efficacy has been the inability to transfuse adequate numbers of perfectly functioning PMNs. Under the stress of a severe bacterial infection, the marrow of an otherwise healthy adult will produce between 10^{11} and 10^{12} PMNs in 24 hours. Granulocyte concentrates collected from healthy donors who are not stimulated with corticosteroids or granulocyte colony-stimulating factor (G-CSF) will contain between 0.2 and 0.8 × 10^{10} PMNs—a woeful number equal to approximately 1% of a healthy marrow's output. Hence donor stimulation is mandatory to achieve even a hope of a reasonable PMN dose per GTX.

Donor stimulation using only properly timed corticosteroids (≥24 hours before leukapheresis, NOT immediately before) will increase the yield to approximately 2 × 10^{10} PMNs. Stimulation with G-CSF, alone or in combination with corticosteroids, will produce higher but variable PMN yields. Yields of 4 to 8 × 10^{10} PMNs are achieved regularly, and posttransfusion blood PMN counts frequently increase to 1 to 3 × 10^9/L, with PMNs detected in the recipient's bloodstream for several hours after GTX. Currently PMN donors are optimally stimulated using 300 to 480 mcg G-CSF given subcutaneously plus 8 mg dexamethasone taken orally approximately 12 hours before beginning leukapheresis.[26] Recent reports suggest that adrenal corticosteroids might cause posterior subcapsular cataracts in PMN donors. Although these reports are not in total agreement, it seems logical to include this cautionary information in donor consent forms or to stimulate PMN donors using only G-CSF—accepting lower PMN doses with the last option.[27]

Each institution must assess local needs. If, despite optimal antimicrobial and other supportive therapy, neutropenic patients suffer significant morbidity or mortality from infections, GTX should be considered. Once therapeutic transfusions have been prescribed, they must be given effectively (≥2 × 10^{10} PMNs per dose with corticosteroid stimulation, ≥4 × 10^{10} PMNs per dose with G-CSF, and never <1 × 10^{10} PMNs per dose). Transfusions are continued until the infection has resolved or until blood PMNs have risen above 1.0 × 10^9/L in the absence of further GTX. It seems logical that patients with evidence of alloimmunization (platelet refractoriness, leukocyte antibodies, repeated febrile transfusion reactions, or posttransfusion pulmonary infiltrates) should receive GTX collected from donors selected to be leukocyte compatible by human leukocyte antigen matching and/or leukocyte crossmatching. However, it has not been clearly shown that attempts to improve leukocyte antigen compatibility do in fact increase the success of GTX in alloimmunized patients—particularly when modern GTX from G-CSF–stimulated donors are transfused. Granulocyte concentrates should be transfused as soon as possible after collection because PMN functions begin to deteriorate rapidly. Some delay between collection and transfusion is inevitable, and granulocyte concentrates are usually stored briefly at 22° C, with little or no agitation. It is highly desirable to transfuse granulocyte concentrates within 6 hours of collection; they should not be given if more than 24 hours old.

0.95 × 10^9/L measured 24 hours posttransfusion. The goals of this study were to evaluate the feasibility and safety of collecting and transfusing PMNs from G-CSF–stimulated donors; patient outcomes were not reported.

Adkins et al[24] transfused 10 allogeneic marrow recipients with PMNs collected from their HLA-matched sibling marrow donors (see Table 115-6). Leukapheresis was performed on days 1, 3, and 5 posttransplant, and GTX were infused. Recipients were given 7.5 mcg/kg G-CSF every 12 hours until blood PMNs were greater than or equal to 1.5 × 10^9/L. Recipient blood PMNs were maintained at greater than 1.5 × 10^9/L throughout the 5 days of posttransplant GTX. By comparison, a historical group of control recipients treated with G-CSF, but no GTX, exhibited lower mean blood PMN counts of less than 0.5 × 10^9/L posttransplant. Prophylactic GTX seemed promising in this setting and perhaps would have been even more effective (i.e., higher recipient blood PMN counts and fewer infections) if given daily.

In another study, Adkins et al[25] transfused 23 autologous peripheral HPC recipients with PMNs collected from first-degree relative donors (see Table 115-6). Leukapheresis was performed on posttransplant days 2, 4, 6, and 8, and GTX were infused. Recipients were given 5 mcg/kg G-CSF daily until the blood PMN count was greater than or equal to 1.5 × 10^9/L. Recipients were studied for the effects of lymphocytotoxic antibodies (i.e., leukocyte alloimmunization) on GTX effectiveness. The 15 recipients who did not exhibit lymphocytotoxic antibodies during the 10-day study period experienced a mean of 4.1 febrile days and required 7.3 days of antibiotics. Values for the eight recipients with lymphocytotoxic antibodies were less desirable—6.3 febrile days and 10.5 days of antibiotics. Rates of documented infections were not reported.

No firm conclusions can be drawn from these reports of modern prophylactic GTX because (1) no nontransfused control subjects were included, (2) few patients were studied, and (3) most patients were given GTX every other day, rather than daily—possibly providing a lower-than-optimal dose of PMNs. Modern prophylactic GTX appear promising, but their efficacy, potential adverse effects, and economic analysis await definition by randomized clinical trials.

ALTERNATIVE OR ADDITIVE MEASURES TO GRANULOCYTE TRANSFUSIONS

Patients with severe neutropenia, particularly those undergoing intense chemotherapy or HPC transplantation, exhibit a variety of abnormalities in multiple body defense mechanisms, most of which cannot be corrected by GTX. Consequently infections that occur in these patients often occur after the period of severe neutropenia and accordingly do not respond to GTX. To bolster body defenses, a number of additional therapies have been evaluated—two of which are the use of recombinant myeloid growth factors (i.e., cytokines) and intravenous immunoglobulin (IVIg).

Recombinant myeloid growth factors such as G-CSF and granulocyte-macrophage colony-stimulating factor (GM-CSF) are glycoprotein cytokines that enhance the production, differentiation, and function of myeloid cells. As previously reviewed, studies of cytokine production in neonates have yielded conflicting results, with investigators reporting values that are higher than, equal to, or lower than adult values. Generally the dysregulation of expression and production of hematopoietic cytokines in neonates contributes to quantitative and qualitative myeloid abnormalities that lead to decreased availability and function of blood PMNs. Several trials of G-CSF and GM-CSF, used to prevent and to treat neonatal sepsis, have been reported. Although most studies have shown some benefit, such as improved production and function of PMNs, reduction in the incidence of infections and/or mortality has not been convincingly shown.

In older children and adult patients, G-CSF and GM-CSF have been used to accelerate marrow recovery after chemotherapy and to successfully diminish the rate of acquired infections and the need for prolonged hospitalization. In contrast to success in preventing neutropenic infections, the role of G-CSF and GM-CSF in treating already established infections is not as firmly documented. Regardless of solid evidence, these growth factors frequently are given to patients with neutropenia and severe infections, and it seems reasonable to consider adding therapeutic GTX when severe bacterial, yeast, or fungal infections are progressing in neutropenic patients, despite the use of appropriate antibiotics plus recombinant cytokines (see box on Author's Approach to Therapeutic Granulocyte Transfusions).

The use of IVIg to prevent or to treat neonatal sepsis has appeal because this therapy may correct developmental abnormalities/delays of humoral immunity and neutrophil function. In studies of experimental infections, IVIg proved beneficial by increasing opsonic activity and by improving PMN kinetics. Although the precise role of IVIg in the management of human infants is controversial, this therapy has been given (with mixed results) to prevent and to treat infections. Most prophylactic studies evaluating IVIg to prevent infections have documented few positive effects, but a few have reported true benefit. In contrast, several therapeutic studies reported benefit from adding IVIg to antibiotics during the treatment of neonatal infections. However, the data remain insufficient to justify the routine use of IVIg as standard therapy to prevent and/or treat infections in all extremely low-birth-weight preterm infants.

Author's Approach to Therapeutic Granulocyte Transfusions

Indicated for severe bacterial, yeast, or fungal infection in a neutropenic patient (<0.5×10^9 polymorphonuclear neutrophils [PMNs]/μL blood) when the infection progresses despite optimal antimicrobial therapy.

Collect PMNs (4 to 8×10^{10}) from allogeneic blood donors, as follows:

1. Stimulate neutrophilia by giving the donor 300 to 480 mcg of granulocyte colony-stimulating factor (G-CSF) subcutaneously 12 hours before beginning leukapheresis, with or without 8 mg dexamethasone orally 12 hours before beginning leukapheresis.
2. Process 10 L of donor blood using a continuous-flow blood separator with citrated hydroxyethyl starch solution infused throughout the collection.

Transfuse one granulocyte concentrate (4 to 8×10^{10} PMNs) daily until bone marrow recovery (blood PMNs >1.0×10^9/L without granulocyte transfusion) or clinical resolution of infection.

CHAPTER 116

PRINCIPLES OF PLASMA TRANSFUSION: PLASMA, CRYOPRECIPITATE, ALBUMIN, AND IMMUNOGLOBULINS

Matthew S. Karafin, Christopher D. Hillyer, and Beth H. Shaz

Plasma and its derivatives are valuable resources, but cost, risk of infectious disease transmission (although rare), and other adverse effects mandate their appropriate use. Plasma can be separated from red blood cells (RBCs) through centrifugation of whole blood at the time of collection or can be collected by apheresis as a single product or as a byproduct of platelet or RBC apheresis. Plasma can be processed into derivatives through cold ethanol fractionation (method of Cohn). In this chapter, the features and uses of plasma products, which include fresh-frozen plasma (FFP); plasma frozen within 24 hours of phlebotomy (PF24); thawed plasma; and plasma derivates, including cryoprecipitate-reduced plasma, cryoprecipitate, albumin, intravenous immunoglobulin (IVIG), and intramuscular immunoglobulin, are discussed. The use of plasma-derived clotting factor concentrates as well as coagulation factor concentrates that are genetically engineered as therapy for specific clotting factor deficiencies are discussed in Chapter 118.

PLASMA PRODUCTS

Plasma is the acellular, fluid compartment of blood, and it consists of 90% water; 7% protein and colloids; and 2% to 3% nutrients, crystalloids, hormones, and vitamins. The protein fraction contains the soluble clotting factors: fibrinogen; factor XIII; von Willebrand factor (vWF); factor VIII primarily bound to its carrier protein vWF; and the vitamin K–dependent coagulation factors II, VII, IX, and X. Clotting proteins are the constituents for which transfusion of plasma is required. Plasma products include FFP, PF24, and thawed plasma, which can be used interchangeably. Notably, FFP and PF24 are both termed FFP in some countries outside of the United States.

Fresh-Frozen Plasma and PF24

Plasma frozen at −18° C or colder within 8 hours of donation (6 hours with the use of some storage bags after apheresis collection) can be labelled as FFP. This product may be stored up to 1 year before use, at which time it is thawed at 30 to 37°C over 20 to 30 minutes. A second type of frozen plasma, the most commonly used in the United States, is PF24 plasma, which is also thawed at 30 to 37C before use. PF24 is frozen at −18° C or colder within 24 hours of collection. If either product is not immediately used it can be stored for 24 hours at 1 to 6°C. The difference between FFP and PF24, using historic data, is a reduction in the following factors: fibrinogen, 12%; factor V, 15%; factor VIII, 23%; and factor XI, 7%. More recently, a direct comparison between FFP and PF24 mean factor activity immediately after thaw revealed the following changes in activity levels: factor II, 0%; factor V, +1%; factor VII, −16%; factor VIII, −15%; factor IX, +6%; factor X, 0%; vWF antigen activity, +34%; vWF : Ristocetin cofactor activity, +22%; fibrinogen, +29 mg/dL; Antithrombin, 0%; protein C, −19%; and protein S, −5%. A disintegrin and metalloproteinase with a thrombospondin type 1 motif, Member 13 (ADAMTS13) activity level is also equivalent in FFP, PF24, and cryoprecipitate-reduced plasma (discussed below). All of the factors evaluated in this study reveal that PF24 immediately after thaw had activities above the minimum activity required for safe surgical hemostasis (factor II, 97%; factor V, 86%; factor VII, 89%; factor VIII, 66%; factor IX, 88%; factor X, 94%; vWF : Ristocetin cofactor activity, 123%; fibrinogen, 309 mg/dL). Therefore, studies support that FFP and FP24 can be used interchangeably.

Thawed Plasma

Even after 1 day, coagulation factors are well maintained in thawed FFP and PF24 stored at 1 to 6° C for up to 5 days, termed *thawed plasma*. Studies show that during 5 days of storage, most clotting factors, including ADAMTS13, remain stable. However, evidence shows that activity levels fall for factors V, VII, and VIII. A review by Eder and Sebock revealed that at day 5, factor V, VII, and VIII activity levels fell from day 1 on average by 16%, 20%, and 41%, respectively, if the FFP was derived from whole blood, and 9%, 4%, and 14%, respectively, if the FFP was derived via apheresis. Although some recent evidence suggests that thrombin generation may be slower in 5-day-old thawed plasma, the decrease in clotting factor activity for both FFP and PF24 is generally not considered to be of clinical significance because the mean factor activity levels for 5-day-old thawed plasma remain above the minimum activity required for safe surgical hemostasis (on average, FFP: factor V, 67%; factor VII, 70%; factor VIII, 43%; PF24: factor V, 59%; factor VII, 77%; and factor VIII, 48%). Stored thawed plasma improves patient care and is more cost effective, due to decreased wastage, than frozen plasma because no preparation time is required. This difference consequently results in a decreased turnaround time and a substantially reduced wastage rate.

Cryoprecipitate-Reduced Plasma

Cryoprecipitate-reduced plasma, also known as cryosupernatant or cryoreduced plasma, is the remaining supernatant after the removal of cryoprecipitate from FFP, which is subsequently refrozen. This product is deficient in factor VIII, factor XIII, vWF, fibrinogen, and fibronectin. Cryoprecipitate-reduced plasma is only indicated in the treatment of patients with thrombotic thrombocytopenic purpura (TTP) and thus cannot be used interchangeably with thawed plasma, FFP, or FP24.

Solvent-Detergent Plasma

Solvent-detergent plasma is a product manufactured from 2500 or fewer pooled plasma products that has been treated with solvent (tri-η-butyl phosphate)/detergent (triton X-100) to inactivate lipid-enveloped viruses (HIV, hepatitis B, hepatitis C). The product is distributed in 200-mL containers and frozen at −18° C with a shelf life of 1 year. This product has approximately 50% loss of protein S and approximately 10% loss of other factors. SD plasma is approved for use by the U.S. Food and Drug Administration (FDA) but is no longer sold in the United States; however, SD plasma is available in other countries. Other pathogen-reduction methods have also been developed, including amotosalen photochemical

treatment, riboflavin-treated plasma, and methylene blue-treated plasma. Studies in Europe show that these methods are also quite effective at reducing the risk of viral contamination, but none is currently FDA approved.

Recovered and Source Plasma (Plasma for Manufacture)

Some plasma products are not used clinically but are used for further manufacturing into plasma derivatives. These products include recovered plasma (liquid plasma and "plasma") that are derived from whole blood and are sent to a manufacturer from a collection facility through a "short supply agreement." Liquid plasma (which can be used clinically) is defined as plasma that is separated from whole blood at any time during storage at 1 to 6° C up to 5 days after the whole blood expiration date. *Plasma* is defined as liquid plasma that is frozen at −18° C or colder with a frozen shelf-life of 5 years. Source plasma, an FDA licensed product, is collected by apheresis, which is intended for further manufacturing. The Plasma Protein Therapeutics Association promotes safe collection and manufacturing practices of plasma derivatives.

Indications

Most guidelines consistently support plasma transfusions for correcting multiple acquired coagulation factor deficiencies, as seen in liver failure, disseminated intravascular coagulation (DIC), massive transfusion, reversal of warfarin effect, and certain indications as a replacement fluid in therapeutic plasma exchange (Table 116-1). There is no current evidence-based laboratory value "trigger" for plasma administration, and any recommendation needs to be weighed against the patient's presence, or risk, of bleeding.

Plasma is typically indicated when the prothrombin time (PT) or partial thromboplastin time (PTT) is greater than 1.5 to 1.7 times normal paired with the presence of bleeding or anticipated bleeding. A variable response to plasma can be largely explained by the nonlinear, exponential relationship between clotting factors activity levels and coagulation test results (Fig. 116-1).

Audits of recent transfusion practices have consistently demonstrated that plasma product use is inappropriately high. Recent estimates suggest up to 83% (reported range, 10%–83%) of plasma transfusions are not administered according to published guidelines. The most commonly cited reason for plasma administration is a preprocedural elevation in coagulation studies. This indication is not evidence based, especially when the coagulation abnormality is mild to moderate. Moreover, plasma should not be used as a volume expander or as a source of nutrients. Clinical situations in which plasma transfusions are used are further defined in the following sections.

Table 116-1 Indications for Plasma Product Transfusion

Indicated
Multiple acquired coagulation factor deficiency
Replacement of an inherited single plasma factor deficiency for which no coagulation factor concentrate exists
Liver failure
Massive transfusion
Disseminated intravascular coagulation
Rapid reversal of warfarin effect
Plasma infusion or exchange for thrombotic thrombocytic purpura and other thrombotic microangiopathies, diffuse alveolar hemorrhage, and catastrophic antiphospholipid syndrome
Not Indicated
Immunodeficiency
Burns
Wound healing
Volume expansion
Source of nutrients

Liver Failure

Patients with severe liver disease may have low levels of the vitamin K–dependent clotting factors (II, VII, IX, and X). These patients develop a prolonged PT and PTT. In addition, the thrombin time (TT) may be prolonged and fibrin split products may be elevated, and in later stages, the fibrinogen level may decrease. Hemorrhage, most often secondary to an anatomic lesion, may be complicated by the coagulopathy resulting from these abnormalities.

Plasma transfusions are indicated during bleeding if the coagulation test results are abnormal. In the absence of anatomic lesions, bleeding does not usually occur until the PT is greater than 16 to 18 seconds or the PTT is greater than 55 to 60 seconds. Plasma products are not recommended prophylactically before a surgical challenge or liver biopsy unless these values are exceeded. In fact, the PT and PTT are poor predictors of surgical bleeding, and mild abnormalities in these coagulation tests may be impossible to correct even with infusion of large quantities of plasma. A recent randomized controlled trial revealed that intranasal desmopressin was both less expensive and as effective as plasma transfusion for patients with liver disease with international normalized ratios (INRs) between 2 and 3 undergoing minor surgery. Orthotopic liver transplantation complicated by preexisting severe liver disease, lack of clotting factor synthesis during the anhepatic stage, massive packed RBC transfusion, and DIC may require large volumes of plasma. Transfusion should be guided by clinical assessment of bleeding, coagulation test results, and thromboelastographic changes.

Massive Transfusion

Massive transfusion is generally defined as receiving 10 or more units of RBCs within 24 hours (or one blood volume). Trauma patients

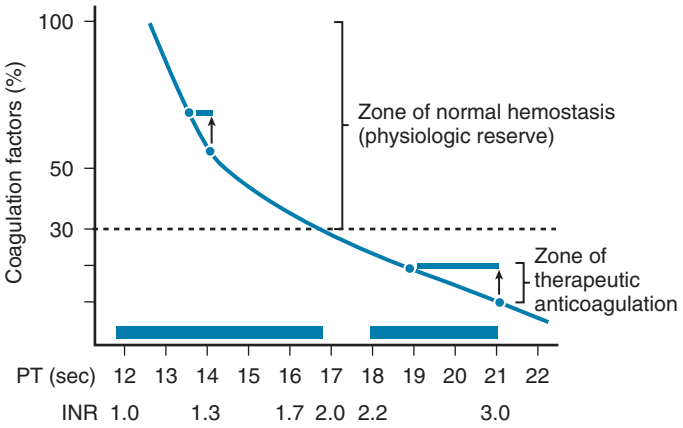

Figure 116-1 RELATIONSHIP BETWEEN FACTOR ACTIVITY LEVELS AND COAGULATION STUDIES. The general relationship between the concentration of coagulation factors and the result of prothrombin time (PT) and international normalized ratio (INR) studies. The normalization of modest elevations in the INR required much larger volumes of plasma than would be expected, and modest doses of plasma can result in marked changes in the INR when markedly elevated. The cause of this phenomenon can be explained by the nonlinear, exponential relationship between coagulation factor concentration and standard coagulation test results. As shown, small increases of coagulation factors correlate with marked changes in coagulation studies when coagulation factors are depleted. The opposite is true when the coagulation factors are at higher concentrations. *(Adapted from Kor DJ, Stubbs JR, Gajic O: Perioperative coagulation management; Fresh frozen plasma.* Best Pract Res Clin Anaesthesiol *24: 51, 2010.)*

may arrive at the hospital with a prolonged PT (termed acute trauma-induced coagulopathy, early trauma-induced coagulopathy, or acute coagulopathy of trauma). Early trauma-induced coagulopathy is associated with increased mortality and increased use of blood products. Trauma patients can also develop a secondary coagulopathy, termed the *lethal triad,* secondary to dilutional coagulopathy, acidosis, and hypothermia. The dilutional coagulopathy is secondary to the administration of crystalloid and RBCs without coagulation factor support. Studies have shown that the early use of plasma and platelets in trauma patients undergoing massive transfusion appears to decrease the incidence of secondary coagulopathy (lethal triad) and improve survival in these patients.

Some experts have previously argued that plasma should be used only in the context of abnormal coagulation study results in massively bleeding patients. However, recent studies have shown that this may not be the most effective approach. Because of the rapidity required to treat severely bleeding patients, standardized hospital-based massive transfusion protocols providing predetermined ratios of RBCs, plasma, cryoprecipitate, and platelets until the hemorrhage is controlled are in use and have been associated with improved survival. Furthermore, massive transfusion protocols identify who is responsible for different aspects of the patient's care, what laboratory tests should be ordered and when, and what blood products should be prepared and at what intervals. Currently, there is no optimal protocol. Some protocols are laboratory based, others have preset blood product volumes and ratios, and some others integrate both. Importantly, hospitals develop these protocols using a multidisciplinary team, defining quality measures with periodic review to adjust the protocols based on new evidence and data.

The optimal ratio of RBC to plasma products in the context of massive transfusion is under active investigation. Multiple studies in both the military and civilian literature have shown a reduction in morbidity and mortality with a transfusion ratio of 1 unit of plasma for every 1 to 3 RBC units transfused in the context of severe posttraumatic bleeding. To date, the sum of available evidence supports the use of this more aggressive plasma transfusion strategy, but survivorship bias remains a concern because of the retrospective nature of most of the studies to date, and some recent studies do not show benefit. Moreover, one European group has recently suggested that the use of prothrombin complex concentrate (PCC) and fibrinogen concentrates, instead of plasma, provides a safer alternative for massive transfusion patients. When published, data from the recently completed Prospective Observational Study of Massive Transfusion Trial (PROMTT), an observational trial including massively transfused trauma patients in 10 civilian trauma centers, will greatly advance knowledge regarding optimization of transfusion ratios.

In the recent past, trauma patients would be provided primarily crystalloid and albumin followed by component transfusion therapy based on specific transfusion "triggers." A hemoglobin below 8 g/dL for RBCs, PT above 1.5 times normal for plasma, platelet count below 50,000/μL for platelet transfusions, and fibrinogen below 100 g/dL for cryoprecipitate were often used. These "triggers" have now been incorporated as part of some massive transfusion protocols as algorithms to guide therapy. In these protocols, component therapy is guided by rapid and regular laboratory value correlation. To improve the speed by which one can address coagulation abnormalities, some protocols now use thromboelastography (TEG) or other point-of-care tests. TEG technology provides a dynamic and global assessment of the coagulation process and can provide rapid assessments of the patient's platelet function, coagulation cascade, and fibrinolysis. The mechanism underlying TEG technology and the interpretation of TEG data are beyond the scope of this chapter. Currently, sufficient data are lacking to universally recommend the use of TEG in massive transfusion protocols.

Massive transfusion in other conditions, such as liver, cardiac, or orthopedic surgery and obstetric hemorrhage, likely has a different pathophysiology; thus transfusion management of these patients may be different than for trauma patients. Studies exploring the use of massive transfusion protocols in these situations are lacking, but institutions should have policies in place for rapid availability of blood products and laboratory testing.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation may be secondary to sepsis, liver disease, hypotension, surgery-associated hypoperfusion, trauma, obstetric complications, leukemia (usually promyelocytic), or underlying malignancy. Successful treatment of the underlying cause is paramount. Recent guidelines suggest that plasma should not be initiated based on abnormal laboratory results alone. Rather, patients with DIC and bleeding, those requiring invasive procedures, and those at risk for bleeding complications should be given plasma in amounts sufficient to correct or ameliorate the coagulopathy or hemorrhagic diathesis. Large volumes of plasma are often necessary to correct the coagulation defect in these patients, and a dose of 30 mL/kg has been suggested. However, in patients with severe liver disease, bleeding, and DIC, plasma infusions often fail to normalize the PT and PTT.

Rapid Reversal of Warfarin Effect

Warfarin inhibits the hepatic synthesis of vitamin K–dependent clotting factors (factors II, VII, IX, and X) by blocking the recovery of the form of vitamin K that is active in the carboxylation of these proteins. Warfarin therapy induces functional deficiencies of these factors, which correct within 48 hours after the discontinuation of warfarin if diet and vitamin K absorption are normal.

The use of plasma in the context of warfarin anticoagulation is well established. Plasma is generally not indicated for warfarin reversal when the patient is not bleeding and when the patient has an INR below 9 because vitamin K administration corrects the coagulopathy in 12 to 18 hours. In patients anticoagulated with warfarin who have active bleeding, require emergency surgery, or have serious trauma, however, the deficient clotting factors can be immediately provided by PCC or plasma transfusions. Plasma use may not be optimal in all situations of warfarin-induced bleeding, though, because large volumes of plasma might be required for adequate warfarin reversal, and lengthy infusion times, especially in those who are volume sensitive, might delay needed surgical intervention.

Consequently, in Europe, PCC should be chosen as first-line therapy for rapid reversal of warfarin anticoagulation, especially if volume overload is a concern. In the United States, though, PCCs do not contain adequate factor VII levels and thus likely need to be paired with plasma transfusions for optimal efficacy. The volume of plasma needed when combined with PCC is still less than that needed when plasma is used alone. Studies have shown that PCC can reverse warfarin-induced coagulopathy faster than plasma or vitamin K alone. However, it is not yet known whether more rapid improvements in coagulation variables afforded by PCC or plasma translate into clinical benefits for the patient (i.e., reduced bleeding) without an increased risk of thromboembolic events. In addition to PCC and plasma, some recent reports support the use of recombinant FVIIa for warfarin reversal in the context of head trauma. Also, INR levels need to be closely followed to ensure that warfarin reversal is sustained.

Thrombotic Thrombocytopenic Purpura and Other Indications During Plasma Exchange

In patients with TTP, plasma exchange with plasma as the replacement fluid is lifesaving. Plasma infusion or exchange is also critical in the treatment of individuals who have congenital TTP. Plasma exchange has decreased the mortality of TTP from more than 90% to less than 10%. Six randomized control trials have demonstrated that plasma exchange is most effective in patients who have an autoantibody to ADAMTS13. This is attributable to both the removal of a patient's plasma containing the inhibitor coupled with the addition of donor plasma containing the functional vWF-cleaving protease. The FDA has approved the use of cryoprecipitate-reduced plasma

for TTP. Some authorities advocate the use of cryoprecipitate-reduced plasma as a first-line therapy for TTP. However, in 2001, the North American TTP Group published a multicenter prospective randomized trial comparing exchange transfusion with plasma and cryoprecipitate-reduced plasma for the initial treatment of TTP, which demonstrated equal efficacy between plasma- and cryoprecipitate-reduced plasma for the initial therapy in TTP.

Plasma exchange is not an established indication for individuals with diarrhea associated hemolytic uremic syndrome (HUS). Plasma exchange with plasma replacement fluid, however, is currently indicated in HUS secondary to a genetic deficiency of complement factor (or plasma infusion) or autoantibody to factor H. Although no randomized control trials have been done to date evaluating the effect of plasma exchange for these cases of HUS, plasma exchange has been theoretically proposed to effectively remove the potentially causative autoantibody or mutated circulating complement regulator while replacing absent or defective complement regulators.

Plasma exchange with plasma replacement may be indicated in other thrombotic microangiopathies. Some medications cause thrombotic microangiopathies, which require plasma exchange. Current examples include ticlopidine and clopidogrel and potentially cyclosporine or tacrolimus. Lastly, plasma exchange with plasma replacement may also be used in the treatment of thrombotic microangiopathy associated with stem cell transplantation and in catastrophic antiphospholipid syndrome.

Plasma as replacement fluid, either partially or completely, for plasma exchange is used in other diseases with risk of hemorrhage caused by the resulting coagulopathy, such as diffuse alveolar hemorrhage, liver failure, and periperatively.

Prophylactic Use of Plasma

Studies have shown that prophylactic administration of plasma to recipients with an INR of 1.5 or less is unlikely to produce a clinical benefit and unnecessarily exposes patients to the risks of plasma transfusion. A number of randomized control trials and meta-analyses have evaluated the efficacy of the prophylactic use of plasma products to reduce the risk of bleeding. One trial, the Northern Neonatal Nursing Initiative Group Trial, randomized 776 neonates and evaluated whether plasma transfusion prophylaxis could prevent intraventricular hemorrhage compared with volume expanders (gelofusin or dextrose saline). In a second large randomized clinical trial, 275 patients were randomized to see whether plasma transfusions could prophylactically prevent bleeding in acute pancreatitis patients. Neither large study showed clinical benefit of prophylactic plasma use. In one systematic review, 55 other randomized clinical trials were reviewed and evaluated. Only 17 of these 55 involved a control group that did not receive plasma. Overall, similar to the two largest studies, the results of these randomized control trials failed to show evidence for the efficacy of prophylactic plasma use across multiple clinical and laboratory outcomes. Similarly, a second meta-analysis evaluated 25 independent studies of minor surgical procedures and found that there was no significant difference in bleeding risk between those who did and did not have a coagulopathy. Despite this evidence, current recommendations still indicate that a pretransfusion INR of 1.6 or above be used as a transfusion trigger because the prophylactic use of plasma is theoretically justified when the clinical risk of bleeding is greater than potential harms of using plasma.

Dosage

One unit of plasma derived from a unit of whole blood contains 200 to 280 mL. When plasma is collected by apheresis, as much as 800 mL can be obtained from one individual ("jumbo" plasma units), but the majority of units clinically used have a volume around 250 mL. If larger units are substituted, then the number of units prepared will decrease proportionally. On average, there is 0.7 to 1 unit/mL of activity of each coagulation factor per milliliter of plasma and 1 to 2 mg/mL of fibrinogen. The appropriate dose of plasma may be estimated from the plasma volume, the desired increment of factor activity, and the expected half-life of the factor being replaced (i.e., factor VII has a half-life of only 4-6 hours, and thus plasma doses should be repeated every few hours if replacing factor VII in a patient with factor VII deficiency). Alternatively, the plasma dosage may be estimated as 10 to 15 mL/kg and ideally should be ordered as the number of milliliters to be infused. The frequency of administration depends on the clinical response to the infusion and correction of laboratory parameters. Moreover, plasma infusions should be given as close to the time as it is needed to allow for its maximum hemostatic effect if given preprocedure.

Compatibility

Plasma is screened for unexpected RBC antibodies during product testing and should be ABO-type compatible for transfusion. Notably, group AB plasma is universally compatible with all patients, and group O plasma is only compatible with patients with group O RBCs.

Adverse Events

Plasma transfusion is associated with a number of infectious and noninfectious adverse events. Transfusion-transmitted diseases traditionally include HIV, hepatitis B, and hepatitis C (see Chapter 121), which are currently rare. Noninfectious risks include allergic reactions, transfusion-related acute lung injury (TRALI), transfusion-associated circulatory overload (TACO), and hemolytic reactions (see Chapter 120).

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury is noncardiogenic pulmonary edema associated with the transfusion of blood products. TRALI is caused by neutrophil and pulmonary endothelial activation, usually caused by transfused donor white blood cell (WBC) antibodies, including human leukocyte antigen (HLA) antibodies and human neutrophil antigen (HNA) antibodies. These donor antibodies react with the recipient's WBCs in the pulmonary vasculature, causing leukoagglutination, activation of the complement cascade, cytokine release, and pulmonary edema. Approximately 5% of TRALI is caused by the opposite mechanisms, which are recipient WBC antibodies against transfused donor WBCs. Nonimmune mechanisms are also postulated to mediate TRALI, including bioactive lipids and CD40 ligand (see also Chapter 120). Lastly, certain patients are at increased risk for TRALI including those with high interleukin-8 levels, liver surgery, chronic alcohol abuse, shock, higher peak airway pressure while being mechanically ventilated, current smoking practice, and positive intravascular fluid balance.

Multiple strategies have been implemented to reduce the risk of TRALI. First, donors implicated in prior TRALI reactions are deferred from further blood donation. Second, multiparous female donors can be tested for HLA and HNA antibodies, and blood products with high-volume plasma (i.e., plasma and apheresis platelets) are not made from those with high-titer antibodies. Third, plasma supplied to hospitals for transfusion can be from male or never pregnant female donors; the parous female plasma is diverted for fractionation. Currently, these strategies have significantly reduced the risk of TRALI without significantly reducing blood product availability.

Allergic Reactions

Allergic transfusion reactions occur when preformed recipient antibodies bind to transfused allergens. Allergic transfusion reactions occur in approximately 1% to 3% of plasma transfusions. Anaphylactic reactions occur in approximately one in 20,000 to 50,000 transfusions. The majority of allergic transfusion reactions are mild. Mild reactions consist of urticaria with or without generalized

pruritus or flushing. More severe symptoms include hoarseness, stridor, wheezing, dyspnea, hypotension, gastrointestinal symptoms and shock. Mild reactions can be treated with antihistamines, and more severe reactions can be treated with epinephrine, H1-receptor antagonists, and steroids (see also Chapter 120).

Transfusion-Associated Circulatory Overload

Transfusion-associated circulatory overload results from vascular fluid volume overload after the transfusion of blood products and is most common in very young or elderly patients with cardiac dysfunction or positive fluid balance. Studies show that the mean age of patients who develop TACO range from about 70 to 85 years. Additional known risk factors for TACO include larger volumes of transfusion, a greater plasma transfusion volume, and a faster transfusion rate. The incidence of TACO is unknown, but it is increasingly recognized clinically. Studies have reported the incidence to range from 1 in 356 to one in 10,000 blood products transfused or 1% to 8% of transfusion recipients, depending on the study population and data collection methodology, and is currently associated with a mortality rate of 5% to 15% in the United States.

Symptoms include dyspnea, orthopnea, cough, chest tightness, cyanosis, hypertension, and headache. Symptoms usually present at the end of transfusion but may occur up to 6 hours after transfusion. Diagnosis is based on the presence of cardiogenic pulmonary edema. Management includes discontinuing transfusion, diuretic therapy, oxygen supplementation, and sitting the patient upright. Avoiding rapid transfusion can prevent TACO unless clinically indicated. Transfusions should be administered slowly, usually 1 mL/kg/hr, particularly in patients at risk for TACO.

CRYOPRECIPITATE

Cryoprecipitate is prepared from 1 unit of FFP thawed at 1 to 6°C. The precipitate is then refrozen and stored at −18° C or colder for 1 year. Cryoprecipitate, volume of 10 to 15 mL, contains 80 to 100 units of factor VIII, 100 to 250 mg of fibrinogen, and 50 to 60 mg of fibronectin as well as vWF and factor XIII.

Cryoprecipitate takes 10 to 15 minutes to thaw at 30 to 37°C and then requires pooling before infusion. Prepooled (pooled before storage) cryoprecipitate products are now available, easing the burden of preparation on the transfusion services. After being pooled and thawed, cryoprecipitate is maintained at 20 to 24°C and outdates in 4 hours (6 hours if unpooled or pooled in a closed system).

Indications

Cryoprecipitate is used predominately to treat bleeding associated with fibrinogen or factor XIII deficiency (Table 116-2). Cryoprecipitate should not be used to treat vWF, factor VIII, and factor XIII deficiencies because virally inactivated factor concentrates are available. Similar to plasma, recent studies also indicate that cryoprecipitate is not used appropriately in clinical practice. One large audit, for instance, demonstrated that across 25 Canadian hospitals and 4370 units of cryoprecipitate transfusions, only 24% of transfusions were considered appropriate, and 34% of cryoprecipitate transfusions were deemed inappropriate according to published guidelines.

Table 116-2 Administration of Cryoprecipitate

Indicated
Fibrinogen deficiency
Massive transfusion
Reversal of thrombolytic therapy
Congenital afibrinogenemia
Dysfibrinogenemia
Factor XIII deficiency
Possibly Indicated
Uremic bleeding
Amniotic fluid embolism (used as last resort to replace depleted fibronectin)
Snake bites

Fibrinogen Deficiency

Fibrinogen deficiency is the primary indication for cryoprecipitate transfusion. The deficiency may be attributable to congenital afibrinogenemia or dysfibrinogenemia, severe liver disease, DIC, or massive transfusion. Patients with the latter indications often have concomitant decreases in clotting factor levels and require the coadministration of plasma products. It is important to obtain fibrinogen measurements because levels below 100 mg/dL cause prolongation of the PT and PTT despite adequate clotting factor replacement. Very low levels of fibrinogen occur during liver transplantation, during which transfusion support with cryoprecipitate is vital.

A specific purified human fibrinogen concentrate is now available and may represent a safer alternative for direct fibrinogen replacement in isolated fibrinogen deficiencies, such as inherited hypofibrinogenemia. Fibrinogen concentrates undergo viral inactivation and have a standardized fibrinogen content; these are used preferentially over cryoprecipitate in some countries, but studies have not demonstrated a clinical benefit over cryoprecipitate. In the United States, fibrinogen concentrate is FDA approved for treatment of bleeding in patients with congenital fibrinogen deficiency.

Fibrin Glue or Sealant

Fibrin glue or sealant results from the mixture of a fibrinogen source (from plasma, platelet-rich plasma, or allogeneic or autologous cryoprecipitate) with a thrombin source (bovine, human, or recombinant). The enhanced local hemostasis achieved by the sealant product is through the action of thrombin on fibrinogen. "Fibrin glue" is a non–FDA-approved thrombin and fibrinogen preparation, and it has been widely used in Europe many years. Fibrin and thrombin sealants are FDA-approved alternatives to fibrin glue and are advantageous over locally made fibrin glues because of standard dosing. Fibrin- and thrombin-containing glues or sealants can be used for multiple surgical purposes, including as a topical hemostat (creating a blood clot to halt bleeding), as a sealant (agents to prevent leakage of potentially nonclotting fluids, such as cerebrospinal fluid), or as an adhesive (bonds different tissues together). Multiple fibrin- or thrombin-containing products are now FDA approved for use.

The safety profile of each product differs depending on the product components and source. Bovine thrombin has been reported to cause anaphylaxis (because of bovine allergies), coagulopathy through formation of antibodies to factor V or II, and rarely death because of severe systemic hypotensive reactions. Consequently, bovine products have an FDA-mandated black box warning on their package inserts. Pooled human plasma sources have the potential risk of viral or prion disease transmission. Reports indicate that hepatitis A and parvovirus B19 are particularly difficult to remove from these products despite current cleansing and filtration methods, and it is recommended that patients be counseled about this risk. Some human plasma products also contain synthetic aprotinin, which is a potential source of allergic reactions. Recombinant products, although eliminating the risk of infectious transmission or antibody formation, may also cause allergic reactions because of the hamster or snake proteins used to manufacture the products. Lastly, autologous fibrin glue preparations have been used, and the infectious risks (e.g., HIV and hepatitis) associated with the use of heterologous fibrin glue are eliminated by replacement with the autologous source but are resource intensive.

Alternatively, albumin mixed with glutaraldehyde has been used to form both an effective sealant and adhesive. The FDA has currently

approved one albumin-based product to seal large blood vessel anastomoses and to reattach layers of the aorta in the context of an aortic dissection. Other successful reported uses include as a sealant in breast cancer surgery and to reduce air leaks in lung volume reduction procedures. Side effects of this compound can be significant, however, and include nerve and muscle necrosis, sinoatrial node damage, calcium metabolism abnormalities, mucosal and skin irritation, adhesive emboli, limitation of aortic growth, and pseudoaneurysms.

Uremic Bleeding

Abnormal bleeding is a common complication of uremia and is primarily attributable to platelet dysfunction and defective interaction with endothelium. Use of cryoprecipitate as a source of vWF has been speculated to correct the platelet dysfunction. However, cryoprecipitate has been shown not to affect platelet aggregation in vitro but does shorten the bleeding time. In 1980, a single study published in the *New England Journal of Medicine* led to the widespread, but temporary, use of cryoprecipitate for the treatment of uremic bleeding. Since that time, variable response reports have been published. Numerous alternative strategies are currently available for the prevention and treatment of uremic-type bleeding including dialysis, erythropoietin, RBC transfusion, desmopressin, and conjugated estrogens, and as such, cryoprecipitate is now rarely used in the prevention or treatment or uremic bleeding.

Massive Transfusion

Although most studies regarding massive transfusion evaluate the use of platelets and plasma, some recent studies suggest that regular doses of cryoprecipitate also help improve survival. One recent study found that a high transfusion ratio involving cryoprecipitate in 214 massive transfusion patients resulted in improved 30-day survival (66% vs. 41%). Another key study found that maintaining a 0.2 g or greater fibrinogen-to-RBC unit ratio resulted in a significantly higher survival rate (76% vs. 48%). They also recommended that 10 units of cryoprecipitate be used for every 10 units of RBCs. Because of survivor bias in these studies, further prospective clinical studies need to be performed to verify these findings. Consequently, although still under investigation, current data tentatively support the use of cryoprecipitate in the context of massive transfusion protocols; however, cryoprecipitate is indicated in the treatment of hypofibrinogenemia.

Dosage

The dosage of cryoprecipitate is calculated on the basis of the amount of fibrinogen present in 1 unit of cryoprecipitate, the plasma volume, and the desired increment. The difficulty in determining the correct amount to administer is primarily attributable to variability in the fibrinogen content of cryoprecipitate secondary to variability in donors and component processing and preparation. The goal of therapy should be to maintain the measured fibrinogen at greater than 100 mL/dL. Consequently, it is estimated that a dose of 8 to 10 units of cryoprecipitate will increase the fibrinogen in a 70-kg adult by 50 to 70 mg/dL. The dosing frequency should be determined based on clinical and laboratory responses because factor XIII and fibrinogen are very stable proteins. Specifically, the half-life of fibrinogen is 4 days, and factor XIII has a half-life of 9 days.

Compatibility

Cryoprecipitate can contain minimal anti-A or anti-B antibodies and, as such, ABO and D compatibility is not necessary for most adult and pediatric patients.

Adverse Events

Cryoprecipitate has similar adverse event risk as other blood products, including transfusion-transmitted diseases, hemolytic reactions, and allergic reactions. Because it contains less plasma and no leukocytes, febrile and allergic reactions are less likely to occur.

ALBUMIN

Albumin, an important plasma protein, contributes primarily to the maintenance of plasma colloid oncotic pressure; it is also involved in the transport of numerous substances, such as unconjugated bilirubin, various hormones, and drugs. The human body content of albumin is 4 to 5 g/kg and is responsible for 80% of the osmotic pressure of human plasma. It is clinically available in four forms: 5% solution in saline; 25% solution in distilled water; albumin conjugated with polyethylene glycol (PEG); and purified protein fraction (PPF), which is 5% total protein (88% albumin and 12% globulins). These products are heat treated, and albumin has not been documented to transmit infectious diseases. (A single outbreak of transfusion-associated hepatitis B occurred with PPF formulation of albumin in 1973.)

Indications

A decrease in measured plasma albumin is found in many situations and is often not a clinically significant concern. Mild edema caused by hypoalbuminemia does not require albumin therapy. However, inadequate synthesis, as seen in severe liver disease and severe malnutrition, or excessive loss, as seen in nephrotic syndrome and protein-losing enteropathy, can lead to significant hypoalbuminemia with intravascular volume depletion, anasarca, ascites, and pleural effusions. Historically, albumin had a broader use (i.e., nutritional support, correction of hypoalbuminemia, volume replacement), but recent studies support its benefit in fewer situations, including nephrotic syndrome resistant to potent diuretic therapy, after large-volume paracentesis, and in ovarian hyperstimulation syndrome (OHSS) (Table 116-3).

Intravascular Volume Expansion

As noted, albumin provides the majority of plasma colloid oncotic pressure. Infused albumin provides colloid oncotic pressure; however, 50% of the infused protein is lost to the extravascular fluid compartment within 4 hours. Crystalloid may also provide volume expansion and is more quickly redistributed into total body fluids. Studies investigating the use of albumin in various situations, including volume expansion during and after surgery, as priming solution in cardiopulmonary bypass, or in maintaining colloid oncotic pressure, found no clinical benefit compared with controls. In 1998, the Cochrane Injuries Group performed a systematic review of randomized control trials in albumin treatment of critically ill patients and concluded that there was no evidence that albumin reduces mortality in patients with hypovolemia, burns, or hypoalbuminemia. They suggested that albumin increases mortality. On the basis of their findings, the group recommended that hypoalbuminemia be eliminated from the list of indications and called for a large randomized trial to assess the effect of albumin on mortality, which has yet to be performed. However, several small prospective studies have argued that albumin is at least clinically equivalent to saline or plasma for intravascular volume resuscitation in some clinical settings.

Thus, the conclusion that albumin has no use in the context of volume expansion and hypoalbuminemia is not definitive.

Table 116-3 Administration of Albumin

Indicated
After large-volume paracentesis
Nephrotic syndrome resistant to potent diuretics
Ovarian hyperstimulation syndrome
Volume or fluid replacement in plasmapheresis
Possibly Indicated
Adult respiratory distress syndrome
Cardiopulmonary bypass pump priming
Fluid resuscitation in shock, sepsis, or burns
Neonatal kernicterus or hyperbilirubinemia
To reduce enteral feeding intolerance
Not Indicated
Correction of measured hypoalbuminemia or hypoproteinemia
Nutritional deficiency, total parenteral nutrition
Preeclampsia
RBC suspension
Simple volume expansion (surgery, burns)
Wound healing
Investigational
Cadaveric renal transplantation
Cerebral ischemia
Stroke
Common Usages
Serum albumin <20 g/dL
Nephrotic syndrome, proteinuria, and hypoalbuminemia
Labile pulmonary, cardiovascular status
Cardiopulmonary bypass, pump priming
Extensive burns
Plasma exchange
Hypotension
Liver disease, hypoalbuminemia, diuresis
Protein-losing enteropathy, hypoalbuminemia
Resuscitation
Intraoperative fluid requirement >5–6 L in adults
Premature infant undergoing major surgery

RBC, Red blood cell.

Cirrhosis

The use of albumin in patients with cirrhosis dates to before 1950. In this setting, albumin is recommended for temporary improvement in hyponatremia; spontaneous bacterial peritonitis; or prevention of the complications associated with paracentesis, including volume shifts and hyponatremia. Several studies demonstrated that after large-volume paracentesis (>5 L), hyponatremia and renal insufficiency were improved with albumin infusion compared with other volume-expanding agents. Moreover, a single randomized control trial of albumin use in cirrhotic patients with spontaneous bacterial peritonitis revealed that albumin administration with antibiotics resulted in reduced mortality and a reduced risk of renal failure compared with antibiotic use alone. Recent studies with albumin infusions have also been done in end-stage liver disease patients for hypoalbuminemia. However, results are less encouraging, with studies indicating no additional benefits or reduction in morbidity.

Nephrotic Syndrome

Albumin has been used to increase colloid oncotic pressure with the intention of increasing diuresis via increasing vascular pressure at the level of the glomerulus. Several studies have shown that albumin use in this context have resulted in no clinical benefit. However, other studies have suggested that albumin use is associated with increased hypertension, respiratory distress, and electrolyte abnormalities. Consequently, the current recommended use of albumin for nephrotic syndrome patients is limited to patients in whom diuretic therapy is poorly tolerated or ineffective or in those with massive ascites or anasarca.

Ovarian Hyperstimulation Syndrome

This syndrome is usually a result of iatrogenic administration of human chorionic gonadotrophin (hCG) to induce ovulation. OHSS is typified by enlarged ovaries, which release vascular endothelial growth factor that can result in increased capillary permeability. This in turn leads to a fluid shift out of the intravascular compartment to the abdominal or pleural spaces, resulting in ascites and hypovolemia. In the most severe form, the patient can develop tense ascites, oliguria, dyspnea, hemodynamic instability, and thromboembolism. Treatment includes fluid restriction, analgesics, and close monitoring; occasionally, hospitalization may be necessary.

Mild OHSS occurs in approximately one-third and moderate to severe in approximately 5% of women receiving exogenous hCG. Increased risk of OHSS includes young age, low body weight, polycystic ovarian syndrome, high dose hCG, high or rapid rise in estradiol level, and previous history of OHSS. In addition, the risk is proportional to the number of developing follicles and number of oocytes retrieved. Moderate to severe OHSS can be mitigated by closely monitoring women during treatment and subsequently withholding or reducing hCG administration when a large number of intermediate-size developing follicles is present or when estradiol levels are elevated.

In 2011, the Cochrane Collaboration systematically reviewed eight randomized clinical trials of albumin administration in OHSS, and concluded that there is only a borderline statistically significant decrease in the incidence and severity of OHSS when albumin was administered during oocyte retrieval in high-risk women. In contrast, the meta-analysis further revealed that the use of hydroxyethyl starch (HES) resulted in a markedly decreased incidence of severe OHSS. Additionally, Bellver et al published a large randomized trial that demonstrated no difference in moderate to severe OHSS when 40 g of albumin was administered after the retrieval of 20 or more oocytes. Only one (nonrandomized) study to date has compared human albumin and 6% HES. This study concluded in 16 patients with severe OHSS that patients who received HES had a higher urine output, needed less abdominal paracentesis, and drainage of pleural effusions and had a shorter hospital stay than patients who received albumin. Therefore, although still clinically used, albumin may be inferior to other therapies in the prevention of OHSS.

Therapeutic Apheresis

Albumin is the replacement fluid of choice for many therapeutic apheresis indications, particularly therapeutic plasma exchange. Albumin compared with plasma replacement for plasma exchange, reduces the risk of adverse events during apheresis procedures by reducing the risk of viral transmission, allergic reactions, and TRALI compared with plasma use (see Plasma section.) Albumin can also be used in combination with saline during apheresis procedures, but excessive use of saline results in hypotensive reactions. Albumin is also indicated if large (>15% of the total blood volume) blood volumes are removed to prevent hypotensive reactions in other therapeutic apheresis procedures (leukapheresis, plateletpheresis).

Although albumin is generally well tolerated in therapeutic apheresis patients, albumin use can result in significant hypotension, bradycardia, and flushing in patients receiving angiotensin-converting enzyme inhibitor (ACE) therapy. ACE inhibitors prevent patients' ability to metabolize bradykinins that are present in the albumin and activated during the apheresis procedure. In patients taking ACE

inhibitors, symptoms can be prevented by using plasma as the replacement fluid or halting ACE inhibitor use and delaying the start of apheresis therapy.

Dose

The volume and speed of administration should be determined by the patient's volume status, condition, and response to the product. A typical adult dose is 25 g, which may be repeated in 15 to 30 minutes. In a 48-hour period, the maximum dose is 250 g. In the pediatric population, albumin dose again depends on the patient's condition, but 0.5 to 1.0 g/kg/dose with a maximum dose of 6 g/kg/day could be used as a general guideline. Albumin 5% is oncotically equivalent to normal human plasma. Albumin 25% provides less infusion volume per amount of albumin and is usually administered to patients with fluid or sodium intake restriction. Albumin 25% expands the blood volume by 3.5 times by drawing fluid into the intravascular space. Five percent Albumin is used for therapeutic apheresis replacement fluid; volume administered depends on volume being replaced during the procedure.

Adverse Effects

Albumin is a plasma derivative used widely and associated with rare adverse reactions. Allergic reactions, including urticaria, may be encountered. Changes in vital signs (heart rate, blood pressure, respiration rate), nausea, emesis, and fever or chills have also been rarely reported. Volume overload and dilutional anemia as well as hypocalcemia may occur. Albumin has not been associated with transfusion-transmitted diseases.

INTRAVENOUS IMMUNOGLOBULIN

Intravenous immunoglobulin (IVIG) is prepared by fractionation of large pools of human plasma. Numerous preparations are available in the United States and throughout the world. Each preparation is slightly different and has theoretical advantages and disadvantages and specific licensed indications. Ideally, IVIG should contain each immunoglobulin G (IgG) subclass; retain Fc receptor activity; have a normal half-life; demonstrate virus neutralization, opsonization, and intracellular killing; and have antibacterial capsular polysaccharide antibody. Furthermore, vasoactive impurities should be absent, and no transmissible infectious agents should be present. The uses of IVIG have been extensively reviewed, and the number of theoretical and accepted uses for IVIG are rapidly expanding.

Indications

Intravenous immunoglobulin is indicated for replacement of immunoglobulins or for its immunomodulatory effects. Currently, there are six FDA-approved indications for IVIG treatment: primary immunodeficiency, pediatric HIV infections, secondary immunodeficiency in chronic lymphocytic leukemia (CLL), idiopathic thrombocytopenic purpura (ITP), Kawasaki disease, and allogeneic stem cell transplantation in patients older than 20 years of age. Some of the FDA indications are no longer applicable, such as in patients with CLL and HIV, given better medications. IVIG is also considered first-line therapy for multiple other conditions, such as Guillain-Barré syndrome, chronic inflammatory demyelinating polyradiculoneuropathy (CIDP), neonatal alloimmune thrombocytopenia (NAIT), posttransfusion purpura, myasthenia gravis, and stiff-person syndrome (Table 116-4). An exhaustive review of all of the known established and investigational uses for IVIG cannot be reasonably summarized in this chapter. For further information, some excellent

Table 116-4 Administration of Intravenous Immunoglobulins

Indicated
Primary immunodeficiency syndromes
Common variable immunodeficiency
X-linked agammaglobulinemia
SCID
Ataxia-telangiectasia
Wiskott-Aldrich syndrome
IgG subclass deficiency
CMV-interstitial pneumonia after BMT
GVHD after bone marrow transplantation
Persistent deficit in antibody production after BMT
Secondary hypogammaglobulinemia
Chronic inflammatory demyelinating polyneuropathy
Chronic lymphocytic leukemia (hypogammaglobinema, high risk for infections)
Guillain-Barré syndrome
ITP
Inflammatory myopathies
Mucocutaneous lymph node syndrome (Kawasaki disease)
Pediatric HIV infection
Parvovirus infection
Stiff-person syndrome
Possibly Indicated
Antiphospholipid syndrome in pregnancy
Autoimmune hemolytic anemia (warm type unresponsive to prednisone)
Factor VIII inhibitors (refractory)
Graves ophthalmopathy
Immune neutropenia
Multiple myeloma (stable disease, high risk for infections)
Myasthenia gravis
Pemphigus
Systemic lupus erythematosus (refractory, severe, active)
Thrombocytopenia refractory to platelet transfusion
Vasculitis (refractory to standard therapy)
Solid organ transplantation (kidney)
Hemolytic disease of the fetus and newborn
Investigational
Acquired von Willebrand disease
Amyotrophic lateral sclerosis
Burn patients
Chronic fatigue syndrome
Fetomaternal alloimmune thrombocytopenia
GVHD
HIV infection
Immune-mediated aplastic anemia
Inflammatory bowel disease
Intractable childhood epilepsy
Multiple sclerosis
Neonatal sepsis
Prevention of nosocomial postoperative infections
Prophylaxis in transplant recipients against CMV infection
Recurrent unexplained spontaneous abortions
Rheumatoid arthritis
Dilated cardiomyopathy
Postpartum cardiomyopathy
Myocarditis
Chronic idiopathic pericarditis
Neonatal hemochromatosis
Parvovirus B19 infection

reviews are cited in the Suggested Readings. A brief summary of some of the more well-established uses of IVIG are presented in the following section.

Primary Immunodeficiency Syndromes

Patients with primary congenital immunodeficiency syndromes have been treated with intramuscular immunoglobulin for the past 30 years. The use of intramuscular immunoglobulin has certain disadvantages, including delayed absorption, delivery of inadequate amounts because of small muscle mass, and pain at the injection site. IVIG overcomes these disadvantages and when used prophylactically in patients with primary immunodeficiency has been demonstrated to reduce the number of febrile and infectious episodes as well as improve survival rate. IVIG use in IgG subclass deficiencies is also beneficial.

Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia may be associated with hypogammaglobulinemia and complications of repeated bacterial infections. IVIG decreases the incidence and severity of bacterial infections in CLL patients with hypogammaglobulinemia and has become accepted prophylactic therapy.

Bone Marrow Transplantation

The use of prophylactic IVIG or cytomegalovirus (CMV)–IVIG in CMV-negative bone marrow (BM) transplant recipients during the first 100 days after transplant has been demonstrated to reduce the incidence of symptomatic CMV-associated disease, including CMV interstitial pneumonia, in some trials. Because of the high cost of this treatment and the increasing use of prophylactic ganciclovir, IVIG is currently not indicated for the prophylaxis of CMV infections in BM transplant recipients. In established CMV interstitial pneumonia, IVIG in combination with ganciclovir has been shown to reduce the mortality rate and has become the recommended treatment modality. Its role in preventing severe graft-versus-host disease (GVHD) is unclear. Prolonged IVIG therapy during GVHD prevention may suppress humoral immunity recovery.

Pediatric Human Immunodeficiency Virus Infection

The defects in humoral and cellular immunity observed in children with HIV infection predispose them to life-threatening bacterial infections. Studies previously demonstrated that the administration of IVIG to HIV-infected children can reduce the incidence and severity of bacterial infections as well as the frequency of hospitalization. More recently, studies have shown that IVIG does not improve outcome likely because of improved medications for HIV and HIV-associated infections.

Idiopathic Thrombocytopenic Purpura

Intravenous immunoglobulin and Rh immune globulin are routinely and effectively used in the treatment of acute and chronic ITP. IVIG significantly raises the platelet count within 5 days in adults with chronic ITP and in children with acute ITP. The mechanism of action of IVIG in ITP is unknown; one postulation is that Fc receptor blockade decreases the removal of antibody-coated platelets. Other proposed mechanisms include suppressed antiplatelet antibody synthesis, increased antiviral immunity, and blockage by antiidiotypic antibodies. In general, IVIG induces responses in most patients within 1 to 2 days. Responses are of variable duration and are rarely sustained, although maintenance therapy may be of some value. IVIG may be effective in chronic ITP refractory to corticosteroids or splenectomy and may show greater efficacy in conjunction with corticosteroids.

Although IVIG has shown equal efficacy with corticosteroids in pediatric acute ITP and in 75% of adults with chronic ITP, because of the transient responses and high cost, its use is justified only in clinical situations requiring rapid elevation of platelet count or if standard therapy has failed. IVIG is therefore indicated in acute bleeding episodes or before urgent surgery, including splenectomy; in patients at high risk of intracranial hemorrhage; and in those in whom corticosteroids are contraindicated or ineffective. IVIG has also been used to treat ITP during pregnancy, postinfectious thrombocytopenia, ITP associated with HIV infection, and neonatal thrombocytopenia. Intravenous anti-D immune globulin (also known as Rh immune globulin) has demonstrated efficacy in Rh-positive, nonsplenectomized individuals with ITP. It has been suggested that the mechanism of action may involve a shift in the immune-mediated destruction from platelets to the antibody-coated RBCs.

Kawasaki Disease

Patients with mucocutaneous lymph node syndrome (Kawasaki disease) have been treated with aspirin with or without concomitant IVIG administration. Coronary artery aneurysm, a serious complication of this disease, was significantly reduced in the IVIG-treated group. However, in a multicenter retrospective survey of all children treated with Kawasaki disease, persistent or recrudescent fever after their first course of IVIG was associated with a statistically significant risk of treatment failure. Furthermore, IVIG retreatment in those patients with persistent fever after IVIG treatment failure was approximately 60%. Current randomized trials are now being done to compare the efficacy of newer, and perhaps better, therapies, such as infliximab (anti–tumor necrosis factor-α). To date, these randomized control studies show that infliximab is at least as safe and as efficacious as IVIG in these refractory patients. One retrospective review has even suggested that infliximab might result in faster resolution of fever and fewer days of hospitalization compared with IVIG. Although studies are still ongoing, IVIG may soon be replaced by alternative therapies in this refractory patient population.

With regard to the pathogenesis of Kawasaki disease, decreased peripheral blood lymphocyte apoptosis has been demonstrated. Therefore, the effect of IVIG in Kawasaki disease has been postulated to partially reverse inhibited lymphocyte apoptosis.

Solid Organ Transplantation

The presence of high-titer reactive antibodies against incompatible graft HLA or ABO antigens increases the risk of early solid organ, antibody-mediated graft rejection and mortality, especially in kidney and cardiac transplants. For some patients who have HLA antibodies to undergo transplantation, these antibodies must be removed or decreased. Although morbidity and mortality can be reduced by selecting an adequately cross-matched donor, IVIG with or without plasma exchange has also been shown to decrease sensitization of incompatible antigens in patients awaiting renal and cardiac transplantations. In addition, IVIG with or without plasma exchange is used in the treatment of biopsy-proven antibody-mediated rejection. One review discussed three randomized control trials that investigated the use of IVIG for renal transplantation and revealed a trend in improvement in desensitization rates and a statistically significant decrease in time to transplant for patients treated with IVIG, superior graft survival rate in kidney transplant patients desensitized with IVIG, and a lower rate of recurrent acute rejection with IVIG compared with OKT3. Consequently, current consensus renal transplant guidelines indicate that IVIG is a useful treatment modality for desensitization of patients with HLA antibodies and in patients with acute rejection.

Randomized trials have not yet been performed for ABO incompatible kidney transplants, or heart, liver, or lung transplants. Moreover, there is a paucity of data for transplant outcomes, and current studies have small numbers without data on donor-specific antibody levels. Current guidelines assert that there is insufficient evidence to make a recommendation for or against the routine use of IVIG for desensitization in these transplants.

Aplastic Anemia Secondary to Parvovirus

Parvovirus B19 infection can result in severe anemia and reticulocytopenia, especially in immunocompromised individuals and individuals with sickle cell disease or thalassemia, and the use of IVIG is considered first-line therapy in the treatment of these patients (typical dose, 0.5 g/kg weekly for 4 weeks).

Chronic Inflammatory Demyelinating Polyradiculoneuropathy

Chronic inflammatory demyelinating polyradiculoneuropathy is a chronic disorder resulting in demyelination of peripheral nerves that result in weakness and sensory changes. Equivalent outcomes have been observed in the treatment of CIDP with IVIG (reported dose, 2.0 g/kg given over 2 to 5 days once each month), plasma exchange, or glucocorticosteroids. The decision as to which treatment to use is made on an individual basis, balancing the risks and benefits of each treatment modality.

Dermatomyositis

Dermatomyositis is a chronic inflammatory disorder that results in progressive weakness and rash. IVIG (typical dose, 2.0 g/kg per month administered over 2-5 days) results in improved muscle strength and neuromuscular symptoms.

Guillain-Barré Syndrome (Acute Inflammatory Demyelinating Polyneuropathy)

Guillain-Barré syndrome is an acute demyelinating peripheral neuropathy affecting both motor and sensory nerves. IVIG (typical dose, 2.0 g/kg given over 1 to 5 days) is likely equivalent to TPE in improving disability and shortening the time to improvement.

Hypogammaglobulinemia Associated With Multiple Myeloma

Multiple myeloma is a monoclonal B-cell (plasma cell) disorder with clinical symptoms arising as a result of plasma cell infiltration of the BM, monoclonal Ig in the blood and urine, and immunosuppression. IVIG has shown to be beneficial in preventing serious infections in plateau-phase multiple myeloma or other hematologic malignancy, when the patients have hypogammaglobinemia, at doses of 0.4 g/kg every 3 weeks.

Immunoglobulin M Paraproteinemic Demyelinating Neuropathy

Paraproteinemic demyelinating neuropathy is a chronic disorder resulting in decreased sensory and motor function, similar to CIDP, in association with monoclonal immunoglobulins. One placebo-controlled trial demonstrated that IVIG may improve short-term morbidity, but the remainder of the available evidence is mixed. The use of IVIG for this condition has recently fallen out of favor with current consensus groups.

Inclusion Body Myositis

Inclusion body myositis is an inflammatory myopathy resulting in chronic muscular weakness. Randomized trials using IVIG appear to result in short-term improvement in strength scores and improved swallowing in patients with inclusion body myositis and is equivalent to treatment with glucocorticosteroids in one small clinical study. The use of IVIG for this condition has also recently fallen out of favor with current consensus groups because of the lack of known sustained benefit for patients with this condition.

Lambert-Eaton Myasthenic Syndrome

Lambert-Eaton myasthenic syndrome results from antibodies to the neuromuscular junction, leading to autonomic dysfunction. One randomized control trial reveals that IVIG significantly improves generalized central and peripheral muscle strength and decreases serum calcium channel antibody titers. A total dose of 2.0 g/kg given over 2 to 5 days is a recommended initial treatment.

Multifocal Motor Neuropathy

Multifocal motor neuropathy is a chronic progressive disorder resulting in primarily hand weakness. IVIG is now considered a first-line treatment for this condition, and improved strength can be seen at a dose of 2.0 g/kg over 2 to 5 days.

Multiple Sclerosis

Multiple sclerosis is a chronic progressive or relapsing and remitting disorder characterized by brain white matter demyelination. There are two published meta-analyses, and several randomized controlled clinical trials in patients with relapsing-remitting multiple sclerosis using a wide range of IVIG doses that demonstrate the success of IVIG in reducing the number of exacerbations and disability in patients with relapsing-remitting multiple sclerosis compared with placebo. However, no studies to date have compared IVIG with standard therapies, and one clinical trial (PRIVIG trial) has raised doubt that IVIG is effective as a routine treatment. Consequently, IVIG is considered a viable second-line option for patients who fail, decline, or are unable to tolerate standard immunomodulatory therapies such as B-interferon and glatiramer acetate.

Myasthenia Gravis

Myasthenia gravis is a chronic neurologic autoimmune disorder characterized by weakness and fatigue upon repetitive skeletal muscle use that improves with rest. IVIG has been used successfully as a short-term measure for acute severe exacerbations of myasthenia gravis at a dose of 2.0 g/kg given over 2 to 5 days and appears comparable to plasma exchange. A definitive randomized control trial comparing the two treatment modalities has not been done, however.

Neonatal Alloimmune Thrombocytopenia

Neonatal alloimmune thrombocytopenia is a rare condition that results from maternal platelet alloantibodies against the fetal or neonatal platelets resulting in neonatal or fetal thrombocytopenia. Studies evaluating the use of IVIG for NAIT are limited but unlikely to improve because of the rarity of the condition. The treatment of NAIT during pregnancy is maternal administration of 1.0 g/kg IVIG weekly as a first-line therapy beginning at 20 to 24 weeks of gestational age with or without the use of glucocorticosteroids. Moreover,

the neonate may need to receive IVIG and platelet transfusions after delivery at a dose of 1.0 g/kg to increase fetal platelet counts to prevent intracerebral hemorrhage.

Hemolytic Disease of the Fetus and Newborn

Hemolytic disease of the fetus and newborn (HDFN) results from maternal RBC alloantibodies binding to fetal or neonatal RBCs and may result in hemolysis, leading to anemia or hydrops fetalis and death depending on the severity. Two meta-analyses reveal that IVIG significantly reduces the need for exchange transfusions in patients with HDFN. IVIG is now consequently recommended at a dose of 0.5 to 1.0 g/kg to treat newborns with HDFN if there is established jaundice and a rising total serum bilirubin despite phototherapy. In addition, maternal IVIG infusion (with or without therapeutic plasma exchange) has been used in severe cases of HDFN in which treatment must occur before the ability to perform intrauterine transfusions.

Posttransfusion Purpura

Posttransfusion purpura (PTP) is a rare complication of transfusion that results in acute, profound thrombocytopenia secondary to platelet antibodies that destroy both transfused and autologous platelets. Although the evidence evaluating the effect of IVIG in these patients is limited to multiple case reports, the available evidence suggests that IVIG should be a first-line therapy for this condition. PTP treatment with IVIG at a dose of 1.0 g/kg over 2 days may result in a rapid increase in platelet count.

Sepsis and Septic Shock in Adults

The use of IVIG in adult patients with bacterial sepsis or septic shock is potentially beneficial. One randomized control trial revealed that in intensive care unit patients with intraabdominal sepsis and shock, IVIG with antibiotics was superior to antibiotics with albumin in improving patient survival. Encouraging results have also been identified in patients receiving IVIG for streptococcal toxic shock syndrome, but further studies are currently needed.

Stiff-Person Syndrome

Stiff-person syndrome is a neurologic disorder associated with truncal and limb rigidity and heightened sensitivity. One small randomized control trial suggests that IVIG could play a positive role in improving stiffness and sensitivity symptoms. Currently, IVIG is considered a second-line therapy for those who fail or cannot tolerate GABAergic medications. A dose of 2.0 g/kg given over 2 to 5 days is the current recommended starting dose.

Dosage

The dosage and frequency for IVIG varies significantly depending on the age of the patient and the clinical indication. Many typical dosages are described in the preceding section. In general, patients require 200 to 800 mg/kg IV every 3 to 4 weeks to achieve adequate IgG levels if immunodeficient (usually 500 mg/dL) and needing protection against infection. Initially, serial IgG level determination may allow the physician to individualize the dose and schedule. These are affected by the recovery, half-life, redistribution, and catabolism of IVIG, which vary from product to product and patient to patient. Patients with ITP are usually initially treated with 400 to 1000 mg/kg/day for 2 to 5 consecutive days with a maximum dose of 2.0 g/kg. Maintenance doses of 400 to 1000 mg/kg/dose every 3 to 6 weeks is recommended in some patients (particularly children) based on clinical response and platelet count. Kawasaki disease is treated with 2.0 g/kg as a single dose in combination with aspirin.

Adverse Effects

Infusions of IVIG should be started slowly, and patients should be closely monitored. If the initial rate (0.5 mL/kg/hr) is well tolerated, the rate can be increased gradually, but not more than eightfold. Fever, headache, nausea, vomiting, fatigue, backache, leg cramps, urticaria, flushing, elevation of blood pressure, and thrombophlebitis may be seen. Adverse events have been reported in 2% to 10% of infusions. IgA-deficient patients may have IgG anti-IgA antibodies, which can cause anaphylactic reactions. This complication is rare and may be avoided by using products with a lower concentration of IgA. Aggregated IgG may produce chills, nausea, flushing, chest tightness, and wheezing. Rarely, IVIG preparations contain RBC antibodies that can produce hemolysis or interfere with serologic evaluations, including RBC compatibility testing. IVIG treatment may produce a positive direct antiglobulin test (DAT), and positive hepatitis and CMV serologies. Serum sickness can also occur. Lastly, high-dose IVIG therapy has been associated with thrombosis, reversible acute renal failure, TRALI, and aseptic meningitis. Improved manufacturing processes currently in place render IVIG free of enveloped and nonenveloped viruses.

HYPERIMMUNE IMMUNOGLOBULIN PRODUCTS

Hyperimmune globulins are concentrated immune globulins with specificity for a specific antigen or group of antigens. These products are manufactured in a similar manner to that used for IVIG product production. However, donors for these specific products are unique in that they have high titers for the Ig specificity of interest. The donor high titers can be achieved via natural immunity, prophylactic immunization, or target immunization, depending on the antibody of interest. These products are generally used to provide passive immunity for a variety of conditions that are described in more detail in the following sections (Table 116-5).

Antithymocyte Globulin

Antithymocyte globulin is a purified concentrated globulin made from hyperimmune serum of horses immunized with human T lymphocytes. ATG is used in renal transplant patients as an adjunct therapy in the treatment of graft rejection. It is also used in patients with aplastic anemia who are not candidates for BM transplantation.

Vaccinia immunoglobulin
Varicella-zoster immunoglobulin
Western equine encephalitis immunoglobulin

ATG, Antithymocyte globulin; *CMV,* cytomegalovirus; *RSV,* respiratory syncytial virus.

Hyperimmune Immunoglobulin

Hyperimmune globulin is used to prevent the development of specific clinical disease or alter its symptomatology. Hepatitis B immunoglobulin is used to provide passive immunity to hepatitis B virus associated with needle stick exposure or sexual contact with hepatitis B surface antigen–positive individuals, after liver transplantation for prevention of recurrence, and prevention of hepatitis B vertical transmission. Other hyperimmunoglobulins include botulism, CMV, hepatitis A, rabies, respiratory syncytial virus, tetanus, vaccinia, and varicella-zoster virus immunoglobulins.

Rh Immunoglobulin

Rh immunoglobulin has two primary indications, prevention of D antigen alloimmunization and treatment of ITP. Rh immunoglobulin is given to D-negative mothers after potential exposure to fetal D positive RBCs, such as after abortion or amniocentesis, as well as at 28 weeks gestational age and postpartum if the child proves to be D positive. The therapeutic effect is thought to be caused by antibody feedback with T-cell suppression of the B-cell clone responsible for the formation of anti-D antibody. Rh immunoglobulin can also be given to prevent immunization in D-negative individuals given D-positive blood products, such as platelets.

Rh immunoglobulin is dosed to adequately prevent D immunization. In the United States, 300 μg are administered after an event resulting in maternal–fetal hemorrhage, at 28 weeks and postpartum. Doses are increased for evidence of large maternal–fetal hemorrhage (300 μg for every 15 mL of RBC exposure). This dosing is also used in the prevention of D alloimmunization after receipt of RBC-containing blood products. Rh immunoglobulin should be given within 72 hours after RBC exposure. Adverse events to low doses, such as those used to prevent D immunization, include fever, chills, and pain at the injection site. Rarely, hypersensitivity reactions are noted.

Rh immunoglobulin doses are substantially higher for the treatment of ITP. They are 50 μg/kg for hemoglobin 10 g/dL or greater and 25 to 40 μg/kg when hemoglobin is 8 to 10 g/dL. Rh immunoglobulin use in ITP is indicated in D-positive patients with intact spleens. Adverse events at high doses of Rh immunoglobulin include hemolysis, DIC, and rarely death.

CHAPTER 117

PREPARATION OF PLASMA-DERIVED AND RECOMBINANT HUMAN PLASMA PROTEINS

David B. Clark

The development of large-scale methods for the preparation of human plasma proteins began more than 70 years ago soon after the outbreak of World War II. The U.S. Armed Forces issued an urgent request to the medical community for 300,000 units of human whole blood or plasma, which appeared to be an impossibly large amount at the time. Thinking that albumin could be used instead of plasma, Dr. Edwin J. Cohn of Harvard Medical School drew together a task force of investigators who developed methods for the fractionation of plasma based on differential precipitation of various proteins with ethanol. After an unsuccessful attempt to use bovine plasma, Cohn was able to obtain a supply of human plasma from the American Red Cross. Although albumin was the only product distributed during the war, the remaining plasma fractions were carefully preserved, and other preparations, including fibrinogen and immunoglobulins, were soon developed. This was the beginning of the plasma fractionation industry.

PLASMA FRACTIONATION

Beginning in the post–World War II era and continuing to the present, major improvements have occurred in the preparation of human plasma protein products. Most large-scale manufacture of plasma-derived products is still based on modifications of the original method developed by Cohn's group supplemented by more selective purification techniques to produce a wide variety of products. In addition, genetic engineering technology has allowed recombinant human plasma proteins to be produced in cell culture systems and transgenic animals. This chapter describes current methods and future directions for the preparation of plasma-derived and recombinant human plasma proteins for clinical use, primarily for products available in the United States.

Plasma is estimated to contain approximately 10,000 different proteins, most of which have yet to be identified. One of the unique features of plasma fractionation is the ability to produce multiple products from a single raw material. Plasma for fractionation is derived from two sources, either directly by plasmapheresis, termed source plasma, or as a byproduct of whole blood donation, termed recovered plasma. The plasma is usually shipped frozen as individual units from local blood or plasma collection centers to a central processing plant.

At the plant, sufficient units to produce typically 2000- to 3000-L pools are thawed slowly at 1° to 5° C to produce cryoprecipitate, a cold-insoluble fraction that contains significant amounts of factor VIII, von Willebrand factor (vWF), fibrinogen, fibronectin, and factor XIII, along with a number of other proteins present in smaller quantities. The cryoprecipitate is usually recovered by centrifugation. The cryo-supernatant or cryo-poor plasma may be treated with a chromatographic media to capture the factor IX complex or antithrombin (AT) before it enters the Cohn process. There it goes through a series of precipitations as the ethanol concentration is increased in steps from 8% to 40% at specific combinations of pH, ionic strength, protein concentration, and cold temperature. The precipitates and supernatants are separated either by the traditional continuous-flow centrifugation or in large-scale filter presses. The method provides both relatively pure fractions containing albumin and immunoglobulins, which need minimal additional processing, as well as fractions enriched in other proteins, which are used as the starting materials for further purification. Fig. 117-1 shows a schematic of the ethanol process.

The first precipitate, fraction I at 8% alcohol, contains factor VIII, fibrinogen, and other poorly soluble proteins. Fractions II and III are precipitated together and contain the immunoglobulins, which are separated in a subsequent series of precipitations to produce fraction II, essentially pure immunoglobulins. Because many of the fraction I proteins are removed in the cryoprecipitate, some manufacturers do not produce a separate fraction I. Instead they collect a combined fraction I + II + III. Fraction IV, produced from the supernatant of fraction (I+)II + III, is sometimes produced in two subfractions. Fraction IV-1 contains the vitamin K–dependent (VKD) clotting factors, AT and α_1-proteinase inhibitor (API), whereas fraction IV-4 contains transferrin, haptoglobin, and some of the albumin. Fraction V is almost pure albumin.

PRODUCT SAFETY

Ensuring the safety of plasma products depends on a complex system that starts with donor selection and carries all the way through to the patient receiving the product. The system is highly redundant so that a failure in one area may be compensated for by another.

Donor Selection, Screening, and Testing

Product safety starts with donor selection. Gone are the days when anyone could be a donor, with prisons and mental hospitals providing much of the country's plasma. Plasma collection centers screen their potential donors rigorously, both for medical history and any social behaviors that might put them at risk of infection. Plasma products licensed in the United States are only produced from plasma collected from U.S. donors in U.S. Food and Drug Administration (FDA)–licensed establishments.

Every donation is tested for a number of different viral diseases by a battery of tests, again with redundancy. Sensitive antigen and antibody tests are followed by NAT testing (nuclear amplification or nucleic acid testing, a form of polymerase chain reaction), which can detect extremely small numbers of virus particles. Because of the "window period" between the time a donor is infected and the time antibodies or viruses can be detected in his or her plasma, most manufacturers also hold donations for at least 60 days until a donor has returned for a repeat donation. If the repeat donation still tests negative several weeks later, there is a high likelihood that the first donation is safe. In addition to FDA oversight, many manufacturers and collection agencies belong to the Plasma Protein Therapeutic Association (PPTA), which has strict quality regulations to help ensure the safety of donated plasma.

Viral Inactivation and Removal Processes

Maximizing the safety of the incoming plasma is only the first step. Viral inactivation and removal methods are now incorporated into

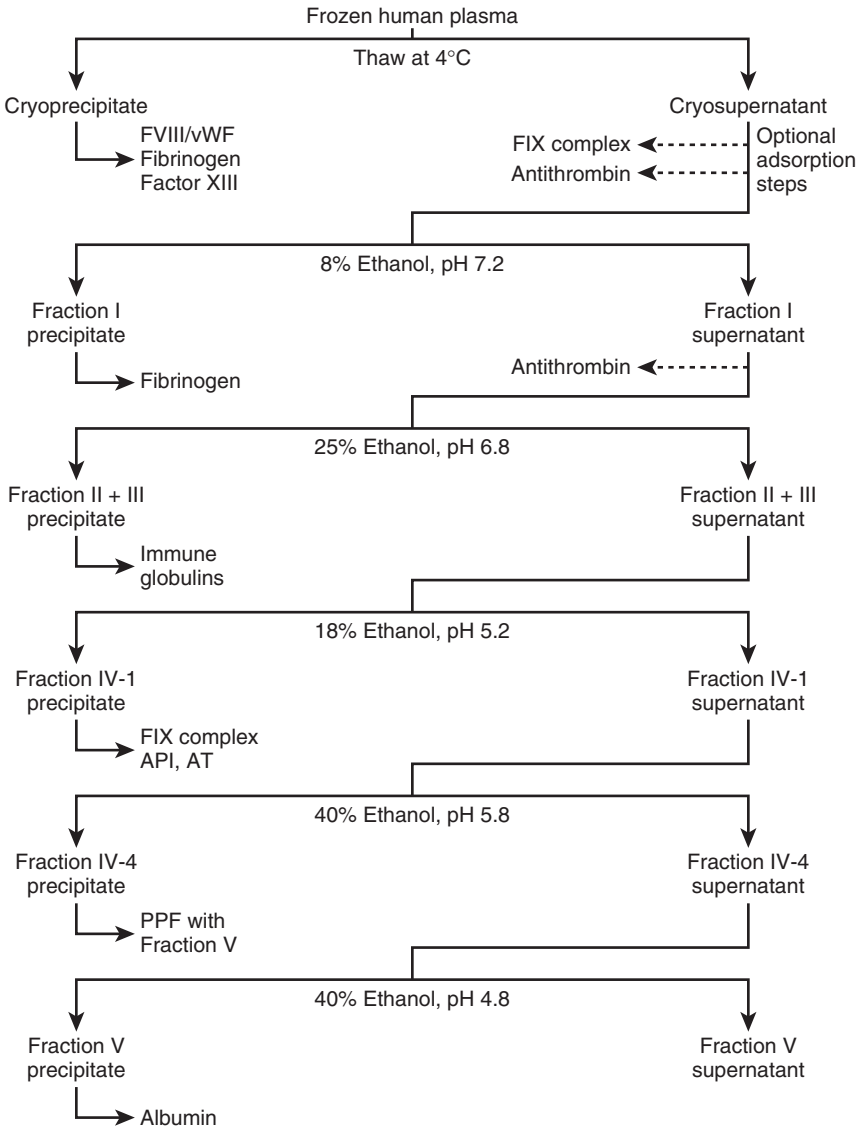

Figure 117-1 SCHEMATIC OF A TYPICAL PLASMA FRACTIONATION PROCESS. The *dashed lines* show optional steps. *API,* α_1-Proteinase inhibitor; *AT,* antithrombin; *FIX,* factor IX; *FVIII,* factor VIII; *PPF,* plasma protein fraction.

all purification processes. One of the early methods, still used today, was pasteurization of albumin; otherwise, except for donor screening and testing, most other early products had no antiviral treatment. That all changed with the AIDS crisis in the early 1980s, when many in the hemophilia community became infected with HIV from clotting factor concentrates.

Since then, many viral inactivation and removal methods have been developed, including various types of heat treatment, solvent and detergent treatment, and nanofiltration. Manufacturers have also realized that many of their purification methods remove viruses, which works well as long as they take steps to protect the treated products from recontamination. Many of those steps also remove prions, the agents of the transmissible spongiform encephalopathies.

The bottom line in all of this is that modern plasma-derived products are extremely safe, as shown both theoretically and by actual experience over the past 25 years. Still, many patients and physicians prefer recombinant products because of their perceived greater safety in terms of the future unknown, emergent virus.

PLASMA PRODUCTS

The following sections provide information about the plasma-derived and recombinant plasma protein products available in the United States in 2011. Additional details, including manufacturing and viral reduction methods, are listed in the tables for most products. The manufacturing methods were taken from prescribing information sheets provided with each product and from the published literature. However, most manufacturers consider their processes proprietary, so some descriptions are not very detailed.

FRESH-FROZEN PLASMA

Whole plasma is still used to treat various conditions, including as a source of coagulation proteins that are not available in purified form and for replacement of significant blood loss. Plasma from a single donor that has been separated from the red blood cells, placed in a freezer within 8 hours after phlebotomy, and stored at 18°C or less is labeled as fresh-frozen plasma (FFP). FFP undergoes essentially the same donor screening and donation testing as plasma for fractionation, but it is not treated for viral inactivation or removal. However, it still has a low risk of infectious disease transmission.

ALBUMIN AND PLASMA PROTEIN FRACTION

Albumin remains one of the major products of human plasma fractionation. Literally tons of albumin have been isolated and millions

of units have been infused. Albumin recovered in very pure form in fraction V is pasteurized in the final vial for 10 hours at 60°C with sodium acetyltryptophanate and sodium caprylate added as stabilizers.

Albumin is a commodity product, with little to distinguish one manufacturer's product from another's. There are small differences in purity, but those are only clinically relevant in rare cases. Three albumin products are manufactured in the United States: albumin (human) 25% solution, albumin (human) 5% solution, and plasma protein fraction (PPF) (human). In albumin (human), more than 96% of the protein content must be albumin, but PPF, obtained by co-precipitating fraction IV-4 with fraction V, has a lower purity of greater than 83% albumin. PPF is more economical to produce than albumin, but the rapid infusion of PPF has been associated with hypotensive episodes.

IMMUNE GLOBULINS AND HYPERIMMUNE GLOBULINS

Since the early 1950s, immune globulin products have been prepared from Cohn fraction II + III by the method developed by Oncley, a collaborator of Cohn. The Oncley process uses additional ethanol precipitations to remove lipoproteins, immunoglobulin A (IgA), IgM, and other plasma proteins, leaving fraction II, which contains purified IgG. Whereas immune globulin is prepared from the plasma of unselected normal donors, hyperimmune globulins are prepared from the plasma of donors with high antibody titers against specific antigens (e.g., rho(D), hepatitis B, rabies, and tetanus). These donors may be identified during convalescent periods after infection or transfusion, or they may be specifically immunized to produce the desired antibodies. The immune globulin products are listed in Tables 117-1 and 117-2.

Intravenous Immune Globulin Concentrates

The original immune globulin concentrates, initially termed immune serum globulin and currently immune globulin (human), were administered by the intramuscular route, with the associated problems of limited injectable volume, poor bioavailability, and discomfort at the injection site. Intravenous (IV) injection of immune serum globulin causes serious clinical reactions, which are attributed to complement-activating aggregates in these products.

To overcome these limitations, immune globulin intravenous (human) (IGIV) products were developed using a variety of methods to remove or inactivate anticomplementary aggregates. Today most

Table 117-1 Immune Globulin Products*

Generic Name	Manufacturer or Distributor	Product Name (Product Form)	Purity IgA Content	Production Methods (Formulation)†	Virus Inactivation or Removal
Immune globulin (human)	Talecris	GamaSTAN S/D (15%-18% solution)	≥96% GG IgA: N/A	CP/CEF (glycine)	Purification steps, S/D, TSE
Immune globulin intravenous (human)	Baxter Healthcare	Gammagard S/D, S/D treatment IgA <2.2 μ/mL in a 5% solution (lyophilized)	≥90% GG IgA <2.2 μg/mL	CP/CEF, IEC (albumin, glycine, glucose, and PEG)	Purification steps, S/D
		Gammagard S/D, S/D treated, IgA <1 μ/mL in a 5% solution (lyophilized)	≥90% GG IgA <1 μg/mL	CP/CEF, IEC (albumin, glycine, glucose, and PEG)	Purification steps, S/D
		Gammagard liquid (10% solution)	≥98% GG IgA ≈37 μg/mL	CP/CEF, IEC (glycine)	S/D, NF, low pH
	Bio Products Laboratory/FFF Enterprises	Gammaplex, 5% liquid (5% solution)	>95% GG IgA <10 μg/mL	CP/CEF, IEC (glycine, sodium acetate, and P80)	S/D, NF, low pH
	CSL Behring	Carimune NF, nanofiltered, lyophilized preparation (lyophilized)	≥96% GG IgA: N/A	CP/CEF, pH 4/pepsin treatment (sucrose)	Purification steps, NF, low pH, DF, TSE
		Privigen, 10% liquid (10% solution)	≥98% GG IgA ≤25 μg/mL	CP/CEF, FAF, IEC (L-proline)	low pH, DF, NF, TSE
	Instituto Grifols/ Grifols Biologicals	Flebogamma 5% DIF (5% solution)	≥97% GG IgA ≤50 μg/mL	CP/CEF, PEG PPTN, IEC (D-sorbitol and PEG)	Purification steps, PEG PPTN, low pH, PST, S/D, NF
		Flebogamma 10% DIF (10% solution)	≥97% GG IgA ≤100 μg/mL	CP/CEF, PEG PPTN, IEC (D-sorbitol and PEG)	Purification steps, PEG PPTN, low pH, PST, S/D, NF, TSE
	Octapharma USA	Octagam, 5% liquid preparation (5% solution)	≥96% GG IgA ≤200 μg/mL	CP/CEF, CHR (maltose)	Purification steps, low pH, S/D
	Talecris	Gamunex-C, 10% caprylate/chromatography purified (10% solution)	≥98% GG IgA ≈46 μg/mL	CP/CEF, FAF, IEC (glycine)	Purification steps, FAF, DF, low pH, TSE
Immune globulin subcutaneous (human)	CSL Behring	Hizentra, 20% liquid (20% solution)	≥98% GG IgA ≤50 μg/mL	CP/CEF, FAF, IEC (L-proline and P80)	Low pH, DF, NF, TSE
		Vivaglobin, 16% liquid (16% solution)	≥96% GG IgA ≤1.7 μg/mL	CP/CEF, FAF (glycine)	Purification steps, PST

CHR, Chromatography (specific method not available); *CP/CEF,* cryoprecipitation/cold ethanol fractionation; *DF,* depth filtration; *FAF,* fatty acid fractionation; *GG,* gamma globulin; *IEC,* ion-exchange chromatography; *IgA,* immunoglobulin A; *N/A,* not available; *NF,* nanofiltration; *P80,* polysorbate 80; *PEG,* polyethylene glycol; *PPTN,* precipitation; *PST,* pasteurization (heat treatment in solution); *S/D,* solvent/detergent; *TSE,* validated for removal of transmissible spongiform encephalopathies. Various forms of filtration and ultrafiltration are common in plasma fractionation, so those steps are not listed.

*These products were marketed in the United States in 2011. Data were obtained from manufacturers, distributors, and available literature.

intramuscular immune globulin usage is limited to hyperimmune products. Although immune globulin products tend to be self-protecting from viral transmission because of the large pools of antibodies they contain, infections have occurred, and as a result, all manufacturers have incorporated viral inactivation or removal steps in the production of IGIV.

The development of IGIV has permitted the administration of much higher doses, with a subsequent expansion in immunoglobulin therapy. Although immune globulin products were originally also considered commodity products, the increased usage has led manufacturers to distinguish their products in various ways. As shown in the tables, products are available in both lyophilized and liquid forms, with various strengths and purities. IgA content and product formulation are also distinguishing factors.

Subcutaneous Immune Globulin Concentrates

The first patient treated for primary immune deficiency was actually given subcutaneous injections of immunoglobulins. However, as already described, intramuscular and later IV injection became the preferred methods. Recently, however, two immune globulin concentrates for subcutaneous injection, termed immune globulin subcutaneous (human), have been marketed. These products are intended for patients who have problems with IV infusion.

COAGULATION FACTOR CONCENTRATES

Transfusion of whole blood was shown in the mid-1800s to curtail bleeding in patients with hemophilia, and by 1940, bleeding episodes were being routinely treated with plasma. However, large amounts of plasma were needed, and this method of therapy could not provide normal levels of coagulation factors without producing hypervolemia. The development of more highly purified plasma-derived coagulation factor concentrates and more recently of recombinant concentrates has resulted in dramatic increases in quality of life and life expectancy for patients with hemophilia. Hemophilia treatment is a large market, and the development of improved coagulation factor concentrates continues to be a major focus of research.

FACTOR VIII CONCENTRATES

Factor VIII is the protein that is missing or defective in patients with hemophilia A. Factor VIII concentrates, generically termed antihemophilic factor (AHF) (human), for the treatment of hemophilia A have evolved from cryoprecipitates to very-high-purity plasma-derived products to recombinant products. The various AHF concentrates available in the United States are listed in Table 117-3.

Table 117-3 Antihemophilic Factor and von Willebrand Factor Concentrates*

Generic Name	Manufacturer or Distributor	Product Name	Specific Activity†	Production Methods	Virus Inactivation or Removal
Antihemophilic factor (human)	Baxter	Hemofil M, monoclonal purified	2-22 ≈2000‡	CP, CAP, IAC, IEC	Purification steps, S/D
	Talecris	Koate-DVI, S/D treated and heated in final container at 80°C	9-22 ≈50‡	CP, AH, PEG PPTN, glycine PPTN, SEC	Purification steps, S/D, HT
	CSL Behring	Monoclate-P, factor VIII:C pasteurized, monoclonal antibody purified	4-10 >3000‡	CP, CAP, AH, IAC, AC	Purification steps, PST
Antihemophilic factor/vWF complex (human)	CSL Behring	Humate-P	1-2 ≈40‡ vWF/FVIII =2.4	CP, AH, glycine PPTN, NaCl PPTN	Purification steps, PST
	Grifols Biologicals	Alphanate	≥5 ≈150‡ vWF/FVIII ≥0.4	CP, PEG PPTN, AC, NaCl PPTN;	Purification steps, S/D, HT, Lyo, TSE
vWF/coagulation factor VIII complex (human)	Octapharma/ Octapharma USA	Wilate	≥60 vWF/FVIII =1.0	CP, AH, IEC, SEC	Purification steps, S/D, HT
Antihemophilic factor (recombinant)	Baxter	Recombinate	2-20 >4000‡	CHO, IAC, IEC	Purification steps
	Bayer (also distributed as Helixate FS by CSL Behring)	Kogenate FS	2600-6800	BHK, IEC, IAC, IMAC	Purification steps, S/D, TSE
Antihemophilic factor (recombinant), plasma/ albumin-free method	Baxter	Advate	4000-10,000	CHO, IAC, IEC	S/D
Antihemophilic factor (recombinant), plasma/ albumin free	Wyeth	XYNTHA (B domain deleted)	5900-9900	CHO, IEC, AC, SEC	Purification steps, S/D, NF

AC, Affinity chromatography; *AH,* aluminum hydroxide adsorption; *BHK,* baby hamster kidney cell culture; *CAP,* cold acid precipitation; *CHO,* Chinese hamster ovary cell culture; *CP,* cryoprecipitation; *HT,* dry heat treatment; *IAC,* immunoaffinity chromatography; *IEC,* ion-exchange chromatography; *IMAC,* immobilized metal affinity chromatography; *Lyo,* lyophilization; *NF,* nanofiltration; *PEG,* polyethylene glycol; *PPTN,* precipitation; *PST,* pasteurization (heat treatment in solution); *S/D,* solvent/detergent; *SEC,* size exclusion chromatography; *TSE,* validated for removal of transmissible spongiform encephalopathies; *vWF,* von Willebrand factor. Various forms of filtration and ultrafiltration are common in plasma fractionation, so those steps are not listed.

*These concentrates were marketed in the United States in 2011. Data were obtained from manufacturers, distributors and available literature. All products are lyophilized.

†IU-factor VIII/μg of total protein.

‡Before addition of human albumin.

Cryoprecipitate

In a landmark discovery for hemophilia A treatment, cryoprecipitate was found in the mid-1950s to contain much of the factor VIII activity of the original plasma. By 1965, single-donor cryoprecipitate with factor VIII concentrations five to 30 times that of plasma became widely available for use in the treatment of patients with hemophilia A. Single-donor cryoprecipitate is still available from many blood banks but does carry a risk of viral transmission.

Intermediate- and High-Purity Antihemophilic Factor Concentrates

The development of AHF concentrates purified approximately 3000-fold over plasma was the next significant advance in the treatment of hemophilia A. Cryoprecipitate was used as the starting material, and a variety of methods were developed to remove fibrinogen, immunoglobulins, and other contaminating proteins. These were the mainstay of hemophilia A treatment for many years and are still available, their chief advantage being lower cost. Some of these products are also indicated as a source of vWF, which circulates in a complex with factor VIII. Products purified 5000- to 20,000-fold over plasma were subsequently developed using various chromatographic methods, but they have primarily been supplanted by immunoaffinity-purified products in the United States.

Immunoaffinity-Purified Concentrates

The next major advance in the preparation of AHF concentrates was the use of murine monoclonal antibodies (mAbs) immobilized on a chromatographic column for the purification of factor VIII. Factor VIII concentrates partially purified by conventional means are applied to an immunoaffinity column that binds either factor VIII directly or the factor VIII–vWF complex. The columns are washed extensively to remove unwanted proteins and then eluted with a solution that disrupts the antibody binding. A final chromatography step removes the harsh elution solutions as well as any mAb that might have leached off the column to produce a factor VIII concentrate that is essentially pure before the addition of albumin as a stabilizer.

Recombinant Antihemophilic Factor Concentrates

One of the remarkable early accomplishments of molecular biology was the elucidation of the structure of factor VIII, its molecular cloning, and the successful production of two recombinant human factor VIII products, Recombinate and Kogenate. Because proper posttranslational processing is essential for factor VIII functionality, the products are produced in mammalian cells, either baby hamster kidney (BHK) cells or Chinese hamster ovary (CHO) cells. The CHO cells used to produce Recombinate also coexpress recombinant vWF, which helps to stabilize the factor VIII and substantially increase its recovery from the culture medium, but is completely removed by subsequent processing. Recombinant factor VIII is purified by various combinations of immunoaffinity chromatography, ion-exchange chromatography, and gel filtration.

One of the major driving forces for development of recombinant products is viral safety; they are seen as inherently safer because they are not produced from plasma. However, the first generation of recombinant products used animal-derived proteins and sera in their cell culture media and in the production of the monoclonal antibodies used for purification, plus human albumin to stabilize the products in the final vial, all potential sources of viral contamination. With this in mind, manufacturers went still further to develop recombinant products completely free of human and animal proteins, both in their production processes and in their formulations. Most current production methods for recombinant products also incorporate viral inactivation or removal procedures for an added measure of safety.

One of the potential benefits of recombinant technology is the ability to design completely new proteins that do not occur in nature, ones that potentially perform better or are easier to produce than their natural counterparts. The factor VIII molecule is a multidomain complex consisting of a heavy chain with A1, A2, and B domains and a light chain consisting of A3, C1, and C2 domains. Previous research had shown that the B domain is not necessary for coagulant activity, so a B domain–deleted product, ReFacto, was developed. Eliminating the B domain, which is highly glycosylated, increased the expression of the molecule as much as 20-fold over full-length factor VIII. ReFacto was subsequently replaced by Xyntha after several improvements, including replacing immunoaffinity purification with a synthetic peptide ligand affinity column.

FACTOR IX CONCENTRATES

Factor IX is the protein that is missing or defective in patients with hemophilia B. Two types of plasma-derived factor IX concentrates are available today: factor IX complex, which contains significant amounts of the other vitamin K-dependent (VKD) clotting factors, and coagulation factor IX (human), a preparation substantially free of these other proteins. A recombinant product, coagulation factor IX (recombinant) is also available. The factor IX concentrates available in the United States are listed in Table 117-4.

Factor IX Complex Concentrates

The VKD proteins are serine proteases that include clotting factors II, VII, IX, and X and the anticoagulants protein C and protein S. Because of their similar structures, they tend to co-purify by most of the methods used to isolate them from plasma. Thus the original factor IX products for treatment of hemophilia B were mixtures of the VKD proteins. Because the protein in highest concentration in these products is prothrombin (factor II), they have also been identified as prothrombin complex concentrates (PCCs); however, factor IX complex is the generic name in the United States.

The VKD proteins were originally adsorbed from either cryo-poor plasma or fraction IV-4 using tricalcium phosphate. Later, ion exchange chromatography resins were used with cryo-poor plasma with the advantage that the supernatant plasma can then be further fractionated by the Cohn method for the production of immune globulins, albumin, and other products with little loss in yield.

Coagulation Factor IX Concentrates

With the widespread use of factor IX complex, it became apparent that serious thromboembolic episodes and acute myocardial infarction were major complications of its infusion, especially when used in large quantities for extended periods, such as for surgical procedures and in patients with liver disease. The cause of the thrombogenicity has not been conclusively determined, but the problem led to the development of more highly purified concentrates that are essentially free of the other VKD clotting factors. These products are designated coagulation factor IX (human). Of the two products available in the United States, one is prepared by immunoaffinity chromatography using a monoclonal antibody to factor IX, and the other is purified by heparin affinity chromatography. These preparations have proven to be largely nonthrombogenic in clinical use.

Recombinant Factor IX Concentrates

A recombinant coagulation factor IX, BeneFIX, has also been developed. It is produced in cell culture by CHO cells that also coexpress furin, a protease that enhances the ability of the cells to remove the amino-terminal propeptide. The factor IX protein secreted into the cell culture medium is purified using several chromatography steps. As

Table 117-4 Factor IX and Other Coagulation Factor and Anticoagulant Concentrates*

Generic Name	Manufacture or Distributor	Product Name	Specific Activity†	Purification Methods	Virus Inactivation or Removal Methods
Factor IX complex	Baxter	Bebulin VH, vapor heated	2	CP/CEF, IEC	VHT

†IU-factor IX/μg of total protein.

with the latest generation AHF products, BeneFIX is produced without human or animal proteins and includes a nanofiltration step to remove any viruses that might be present. The final product has been shown to be structurally and functionally similar to plasma-derived factor IX. However, it has a lower recovery when infused into patients, apparently because of differences in posttranslational glycosylation.

OTHER COAGULATION AND ANTICOAGULANT CONCENTRATES

Now that the risk of infection has essentially been eliminated, the major complication in hemophilia treatment is the development of inhibitors, antibodies directed against factor VIII or factor IX. Low-titer inhibitors can usually be saturated by administering large amounts of factor VIII or factor IX, but this is not an effective therapy for higher-titer inhibitors. There are two primary means of treating bleeding in inhibitor patients, both based on administration of activated clotting factors. Many of the clotting factors circulate as inactive zymogens that are only activated as needed in the coagulation cascade.

Factor IX complex was known to be somewhat effective in preventing bleeding in inhibitor patients, possibly because it contains small amounts of activated clotting factors. That may be the same reason that it can be thrombogenic, but that idea has not been proven conclusively. Based on that information, two activated factor IX complex products were developed, one of which, FEIBA, is still available. FEIBA, which is named for factor eight inhibitor bypassing activity, is generically named anti-inhibitor coagulant complex and is indicated for inhibitor treatment in both hemophilia A and B.

The hypothesis that administration of activated clotting factors can bypass inhibitors also led to the development of NovoSeven, a recombinant activated factor VII concentrate. NovoSeven is produced in tissue culture in BHK cells and purified by ion-exchange and immunoaffinity chromatography. It spontaneously activates during the final ion-exchange chromatography steps. NovoSeven has been extensively studied and is currently the most widely used option for inhibitor treatment, especially for patients who have never been exposed to plasma-derived products. However, both FEIBA and NovoSeven do carry a risk of thromboembolic complications. FEIBA and NovoSeven are listed in Table 117-4.

von Willebrand disease (vWD), caused by missing or abnormal vWF, is actually the most commonly inherited coagulation disorder. vWF is a large protein that circulates in a complex with factor VIII. It stabilizes factor VIII in the bloodstream but also has coagulation functions of its own. There are several types of vWD, some of which behave similarly to hemophilia A because of the missing protection for factor VIII. Several intermediate-purity viral-inactivated AHF concentrates that contain significant amounts of vWF are also indicated for replacement therapy for vWD. These vWF/AHF concentrates are listed in Table 117-3.

Fibrinogen is the final protein in the coagulation cascade. It is cleaved by thrombin to form fibrin, a protein that naturally self-associates to form a clot. RiaSTAP is a plasma-derived concentrate for replacement therapy in fibrinogen-deficient patients that is made from the concentrated fibrinogen in cryoprecipitate. Interestingly, fibrinogen was also one of the first plasma products used, but it was soon taken off the market because it almost universally transmitted viral infections. RiaSTAP is pasteurized (heat treated) in solution for 20 hours at 60°C, twice as long as the typical treatment for

pasteurized plasma products. Significant viral removal has also been demonstrated for its purification process, and the resulting product is considered safe.

Factor XIII does not participate directly in the coagulation cascade but instead stabilizes the final clot by cross-linking the fibrin molecules. Factor XIII deficiency is rare and is characterized by weak clots prone to rebleeding. Patients deficient in factor XIII have hemarthroses and deep tissue bleeds. Before the availability of factor XIII concentrates, patients were usually treated with plasma or cryoprecipitate, both of which carry a risk of viral infection. Corifact, the only factor XIII product available in the United States, is purified from cryoprecipitate and employs a unique process step using Vitacel, a wheat-based vegetable fiber, to remove fibrinogen, after which the factor XIII is further purified by ion exchange chromatography. The final product is pasteurized. RiaSTAP and Corifact are listed in Table 117-4.

Anticoagulant Concentrates

Antithrombin III, now generally just called antithrombin (AT), is an anticoagulant. As its name suggests, it inhibits thrombin (activated factor II), but it also inhibits the activated forms of factors IX, X, XI, and XII. It belongs to the serpin family named for their activity as serine protease inhibitors. Heparin is a cofactor that increases the native activity of AT significantly, from 500- to 1000-fold for factor Xa inhibition up to one million–fold for factor IXa inhibition. The clinical utility of heparin as an anticoagulant is because of its cofactor activity; in the absence of AT, heparin has little effect.

The affinity of AT for heparin is also used to purify the protein by affinity chromatography on an immobilized heparin column. Thrombate III, the only plasma-derived product currently on the U.S. market, is purified by heparin affinity chromatography from Cohn fraction IV-1, but as shown in Figure 117-1, AT is also found in cryo-poor plasma or Cohn fraction I supernatant. ATryn, a recombinant AT, was the first recombinant human plasma protein produced in transgenic animals to be approved anywhere. It is made in the milk of goats and also purified by heparin affinity chromatography. The two available AT concentrates are listed in Table 117-4.

Protein C is a serine protease with a structure similar to clotting factors II, VII, IX, and X, but it is an anticoagulant that cleaves activated factors V and VIII. Patients deficient in protein C are susceptible to thrombosis. One plasma-derived protein C concentrate, CEPROTIN, is available. A recombinant human activated protein C, Xigris, is also available, but it is not indicated for treatment of protein C–deficient patients. It is intended for treatment of severe sepsis, but its efficacy is controversial. The two protein C products are listed in Table 117-4.

Fibrin Sealant and Thrombin

Fibrinogen and thrombin are also used as topical hemostatic agents, together as fibrin sealant and as stand-alone thrombin concentrates. The fibrin sealant and thrombin products available in the United States are listed in Table 117-5.

Fibrin sealant uses the clot-forming reaction of thrombin and fibrinogen to form a physiological glue or sealant that has become widely used in surgical procedures. All three fibrin sealant products on the U.S. market are made from human plasma–derived fibrinogen and thrombin. Fibrinogen is purified directly from cryoprecipitate followed by further purification steps. ARTISS and TISSEEL contain a plasmin inhibitor, synthetic aprotinin, which is a non–animal-sourced product, to delay clot lysis. EVICEL contains a more highly purified fibrinogen component that has minimal plasmin activity and therefore does not contain a clot lysis inhibitor. Both fibrinogen preparations contain residual factor XIII for clot stabilization, and additional factor XIII is recruited from the patient's bloodstream during use.

Table 117-5 Fibrin Sealants and Thrombin Concentrates*

Generic Name	Manufacturer or Distributor	Product Name (Product Format)	Purification Methods	Virus Inactivation or Removal Methods
Fibrin sealant (human)	Baxter	ARTISS (frozen solution and lyophilized powder)	Fibrinogen: CP, OS Thrombin: IEC, CA	Both components: purification steps, VHT, S/D
		TISSEEL (frozen solution and lyophilized powder)	Fibrinogen: CP, OS Thrombin: IEC, CA	Both components: purification steps, VHT, S/D
	OMRIX/Ethicon	EVICEL (frozen solution)	Fibrinogen: CP, AH, HIC, AC Thrombin component: CP, IEC, CA	Fibrinogen component: S/D, PST Thrombin component: S/D, NF
Absorbable fibrin sealant patch	Nycomed/Baxter	TachoSil (lyophilized [equine collagen sponge coated with fibrinogen, thrombin, and albumin])	Fibrinogen: CP, glycine PPTN, AH, HIC, AC Thrombin: CP, CHR, AS, CTA Albumin: CEF	Fibrinogen and thrombin: purification steps Albumin: PST Collagen: low pH, GI Final product: GI
Thrombin, topical U.S.P. (bovine origin)	GenTrac/King Pharmaceuticals (Pfizer)	Thrombin-JMI (lyophilized)	Thrombin: BP, IEC, thromboplastin activation, NF Bovine thromboplastin: GBL, MHA, AS	Purification steps, NF, TSE
Thrombin topical (human)	OMRIX Biopharmaceuticals/ Ethicon	EVITHROM (frozen solution)	CP, IEC, CA	S/D, NF
Thrombin, topical (recombinant)	ZymoGenics	RECOTHROM (lyophilized)	CHO, enzymatic activation, AC, IEC	S/D, NF

AC, Affinity chromatography; *AH,* aluminum hydroxide adsorption; *AS,* ammonium sulfate precipitation; *BP,* bovine plasma; *CA,* calcium activation; *CEF,* cold ethanol fractionation; *CHO,* Chinese hamster ovary cell culture; *CHR,* chromatography (specific method not available); *CP,* cryoprecipitation; *CTA,* citrate activation; *GBL,* ground bovine lung tissue; *GI,* gamma irradiation; *HIC,* hydrophobic interaction chromatography; *IEC,* ion-exchange chromatography; *MHA,* magnesium hydroxide gel adsorption; *NF,* nanofiltration; *OS,* other steps, not specified; *PPTN,* precipitation; *PST,* pasteurization; *S/D,* solvent/detergent; *TSE,* validated for removal of transmissible spongiform encephalopathies; *VHT,* vapor heat treatment. Various forms of filtration and ultrafiltration are common in plasma fractionation, so those steps are not listed.
*These concentrates were marketed in the United States in 2011. Data were obtained from manufacturers, distributors, and available literature.

Thrombin is purified from prothrombin (factor II) in the factor IX complex captured by ion exchange from cryosupernatant plasma. Prothrombin is autocatalytically activated to thrombin in the presence of calcium. Both the fibrinogen and thrombin components are also treated for viral inactivation and removal.

Three stand-alone thrombin products are also available for use in promoting topical hemostasis. For years, bovine thrombin was the standard of care for such use; however, research has suggested that it may have been responsible for postsurgical hemostatic problems in some patients. The cause was apparently contamination with bovine factor V, against which some patients developed antibodies that cross-reacted with their own human factor V. Most bovine thrombin products were taken off the market, but Thrombin-JMI, the sole remaining bovine product, was instead further purified to reduce bovine factor V to undetectable levels. A plasma-derived human thrombin product, EVITHROM, was also developed, which is the same thrombin used in EVICEL fibrin sealant.

A recombinant human thrombin product, RECOTHROM, is another example of a bioengineered protein. The VKD clotting factors contain a domain called the Gla region that is rich in a unique amino acid, γ-carboxyglutamic acid (Gla). The posttranslational modifications required to produce the Gla residues are a rate-limiting step in the production of all of the VKD proteins in cell culture. Presence of the Gla region is absolutely necessary for the function of most of the clotting factors but not for thrombin. Therefore, the Gla-less molecule prethrombin-1 is actually produced in the CHO cells, with a significant increase in production rate. Prethrombin-1 is activated to thrombin using a proprietary enzyme system. RECOTHROM behaves similarly to human and bovine thrombin in clinical use.

PLASMA PROTEINASE INHIBITORS

The proteinase inhibitors that are present in human plasma play critical roles in the regulation of the coagulation, fibrinolytic, complement, and kinin cascade systems. Most of these inhibitors have similar amino acid and structural properties and are members of a superfamily of proteins called serpins (serine proteinase inhibitors). AT, an anticoagulant, was discussed earlier. Two other proteinase inhibitors, API and C1 esterase inhibitor, are also available for treatment of deficient patients. These concentrates are listed in Table 117-6.

α_1-Proteinase Inhibitor

α_1-Proteinase inhibitor (human), also known as α_1-antitrypsin, was the first of the serpins to be isolated and characterized. Although the protein was originally named for its antitrypsin activity, its primary physiologic function appears to be the inhibition of neutrophil elastase in the lung. Patients with hereditary deficiencies of this inhibitor develop pulmonary emphysema and liver disease. API replacement therapy is indicated for chronic treatment of individuals with hereditary deficiency. However, even with four products available, the supply is tight because of the limited amount ultimately available from plasma. One issue is the poor efficiency of IV administration. It is estimated that only approximately 2% of the infused API ends up in the lung. Studies have suggested that aerosol delivery of API directly into the lungs by inhalation would be efficacious and could replace IV administration because of its lower cost and greater convenience. API is also a good candidate for recombinant production.

C1 Esterase Inhibitor

C1 esterase inhibitor acts as a regulator in the complement and fibrinolytic systems and as an inhibitor of factor XIIa and kallikrein. Its name comes from its inhibition of the complement proteins C1r and C1s. Patients deficient in C1 esterase inhibitor are at risk for attacks of hereditary angioedema. Two plasma-derived C1 esterase inhibitor concentrates were licensed in the United States in 2008 and 2009 after being available in Europe for a number of years. CINRYZE is indicated for prophylactic replacement therapy for prevention of hereditary angioedema, while Berinert is only indicated for acute treatment of hereditary angioedema. The products are listed in Table 117-6, but detailed descriptions of their manufacturing processes are not available.

FUTURE DIRECTIONS

New Plasma-Derived Concentrates

With licensure of a number of new products in the past few years, including protein C, vWF, factor XIII and C1 esterase inhibitor, the United States is catching up with Europe and other parts of the world. Concentrates of factor VII and factor XI are also available elsewhere.

Table 117-6 Alpha$_1$-Proteinase Inhibitor and C1 Esterase Inhibitor Concentrates

Generic Name	Manufacturer or Distributor	Product Name (Product Format)	Potency* Specific Activity (SA)	Purification Methods	Virus Inactivation or Removal Methods
Alpha$_1$-proteinase inhibitor (human)	Baxter	Aralast NP, S/D treated, nanofiltered (lyophilized)	≥16 mg API/mL ≥0.55 mg/mg-protein	CP/CEF, PEG PPTN, $ZnCl_2$ PPTN, IEC	Purification steps, S/D, NF
	CSL Behring	Zemaira (lyophilized)	≈50 mg API/mL ≥0.7 mg/mg-protein	CP/CEF, EXTN, DST, IEC, HC	PST, NF
	Kamada/Baxter	GLASSIA (liquid)	20 mg/mL SA: N/A	CP/CEF, CHR	S/D, NF
	Talecris	Prolastin-C (lyophilized)	≈50 mg API/mL ≥0.7 mg/mg-protein	CP/CEF, PEG PPTN, IEC	Purification steps, S/D, NF, TSE
C1 esterase inhibitor (human)	CSL Behring	Berinert (lyophilized)	N/A	HIC, IEC, AS	Purification steps, PST
	Sanquin Blood Supply Foundation/ViroPharma Biologics	CINRYZE (lyophilized)	N/A	CHR, PEG pptn	Purification steps, PST, NF

Various forms of filtration and ultrafiltration are common in plasma fractionation, so those steps are not listed.
*These concentrates were marketed in the United States in 2011. Data were obtained from manufacturers, distributors, and available literature.

Several other proteins in plasma would be potentially useful as therapeutic products, including butyrylcholinesterase for reversal of succinylcholine-induced apnea and treatment of cocaine overdose and other coagulation factors and inhibitors, such as factors X and XII and protein S. However, the prevalence of these disorders is small, so they would be true orphan drugs with limited markets. There are also potential improvements that can be made to current plasma-derived and recombinant concentrates. In addition to enhanced purification and viral clearance methods, products can be made more user friendly. For instance, prophylactic treatment of hemophilia A and B currently requires infusions every 2 or 3 days because of the short natural half-lives of the proteins in the circulation. Several companies are developing factor VIII and IX products with longer half-lives by coupling the molecules to polyethylene glycol, the immunoglobulin Fc domain, or albumin.

Alternate delivery systems could also potentially improve the utility of many products. Delivery of clotting factors by inhalation, ingestion, and subcutaneous injection has been explored. As mentioned earlier, several studies have looked at aerosol delivery of API. Production of fibrin sealant in a powder form that could be sprinkled on a wound has also been studied.

Recombinant Plasma Protein Concentrates

Almost all plasma proteins licensed for human use have been cloned and expressed in biologically active form in animal cells in the laboratory, and several have been developed into licensed products, as described earlier. The main advantages of recombinantly produced proteins include freedom from human viruses and a potentially unlimited supply. AT has already been produced in the milk of transgenic animals, and others such as API, which are required in relatively large amounts, are also candidates. Transgenic cows, goats, pigs, and sheep can produce large quantities of human proteins, typically 1 to 10 g/L in milk. In contrast, animal tissue culture systems routinely produce substantially less protein, typically 0.01 to 0.1 g/L.

Recombinant proteins can also be produced in modified forms that may give them advantageous new properties such as increased potency, longer half-lives, or varied specificity. One product already available is B domain–deleted factor VIII described earlier.

CHAPTER 118

TRANSFUSION THERAPY FOR COAGULATION FACTOR DEFICIENCIES

Elizabeth Roman, Peter J. Larson, and Catherine S. Manno

This chapter reviews products available to treat deficiencies of plasma coagulation proteins. The development of blood component therapy and subsequently protein concentrates that are enriched in particular coagulation factors and other proteins made possible the effective treatment of bleeding episodes in patients with hemophilia and other diatheses. In the 1940s, a collaborative effort funded by the U.S. government was undertaken among protein scientists with the goal of rapidly developing a method to isolate albumin from human plasma to provide a lyophilized intravascular volume expander for use in the military. As part of this effort, Dr. Edwin Cohn developed an ethanol fractionation procedure that was amenable to large-scale manufacture.[1] Building on the foundation of the Cohn fractionation procedure (see Chapter 117), the first coagulation factor concentrates were developed in the mid-1960s and provided a safer and more effective treatment for patients with the X-linked coagulation deficiencies, hemophilia A and B. Given the limited human plasma resource as a raw material for production of all but a few coagulation protein concentrates, manufacturers of human plasma–based products attempt to derive the maximum yield from each pool of plasma. Manufacturers of plasma-derived products strive to maximize the therapeutic potential of pooled human plasma by deriving more products from these processes.

Development of recombinant products has been fueled by concerns of infectious disease transmission through the human plasma resource. Currently licensed products are produced in mammalian cell culture to optimize necessary posttranslational modifications required for biologic activity. These recombinant expression processes are complicated and expensive. Transgenic recombinant technology is currently being explored as a way to decrease or eliminate reliance on the human plasma resource and the technically rigorous production of recombinant proteins using mammalian cell culture methods.

HEMOPHILIA A AND B

The hemophilias are X-linked disorders caused by deficiencies of either factor VIII (hemophilia A, or classic hemophilia) or factor IX (hemophilia B, or Christmas disease). The genes for these coagulation factors are located in close proximity on the long arm of the X chromosome. Whereas hemophilia A affects one in 10,000 males, hemophilia B affects one in 30,000. This difference in incidence is roughly correlated with the size of the genes, and more than 30% of cases arise from spontaneous mutations.

The major morbidity of the severe hemophilias A and B is arthropathy, developing over the course of years in untreated or undertreated adults as a result of recurrent spontaneous joint bleeding. The major cause of hemorrhagic mortality is bleeding into critical closed spaces (e.g., intracranial or retroperitoneal).[2] Central nervous system (CNS) bleeding occurs in 3% to 14% of patients, and mortality from CNS hemorrhage ranges from 20% to 50%[3-5] with neurologic sequelae (including seizures, motor impairment, or mental retardation) observed in 40% to 50% of survivors.[3] CNS bleeding episodes occur predominantly in patients with severe disease (<1% factor level).[3] A more detailed discussion of the hemophilias and the molecular biology of factors VIII and IX can be found in Chapters 137.

TRANSFUSION THERAPY OF HEMOPHILIA A AND B

History of Transfusion for Hemophilia

Transfusion was first proposed by Schönlein and his student Hopf in 1832 as a treatment for "bleeders" who were suffering from exsanguinating hemorrhage, and these two were likely the first to have used the term *Haemophilie* to describe the disease.[6,7] The first effective transfusion-based intervention for hemophilia is credited to Samuel Lane who, in 1840, infused 10 to 12 oz of fresh human blood into a 12-year-old boy with postoperative hemorrhage after eye surgery for correction of a squint.[8] Subsequently, a variety of interventions using the infusion of human and animal blood and blood derivatives were used in the therapy of hemorrhage in patients with congenital bleeding diatheses (Table 118-1). Citrated plasma was first used in 1923 for the treatment of hemophilia by Feissly to overcome a major ABO incompatibility in a father-to-son transfusion.[9] Development of modern blood banking in the 1930s and expansion of transfusion during and after World War II allowed for more widespread use of whole blood and subsequently frozen plasma in the treatment of hemophilia. Because of limited availability, the use of whole blood and components of whole blood for the treatment of hemophilia and other diseases was initially confined to larger metropolitan areas. In addition, volume constraints with the infusion of whole blood and plasma made the achievement of high plasma levels of coagulation factors (>5%) difficult.[10]

The advent of modern transfusion therapy for hemophilia came with the observation that the cold-insoluble precipitate remaining after thawing of frozen plasma at 4 °C contains high concentrations of factor VIII.[11] Application of this procedure to the separation of components of whole blood[12] allowed for the production of a low-volume blood product known as *cryoprecipitate*. Cryoprecipitate derived from a single whole blood collection contains approximately 125 U of factor VIII and quickly replaced frozen plasma as the therapy of choice for the treatment of bleeding episodes in hemophilia A in the 1960s. The availability of cryoprecipitate made the treatment of bleeding episodes by patients in their homes, rather than at a hospital, a reality. In addition, the development of quantitative assays for factor VIII[13] and for factor IX[14] meant that the two diseases could now be distinguished and effects of transfusion therapy on circulating levels of factors could be more accurately assessed.

Before the discovery of plasma cryoprecipitate, significant advances had been made in the fractionation of plasma using ethanol,[1] glycine,[15] polyethylene glycol,[16] a combination of glycine and polyethylene glycol,[17] and calcium or barium[18-20] to precipitate plasma proteins. These techniques, in conjunction with cold precipitation of frozen plasma, laid the groundwork that resulted in the production of the first factor VIII and factor IX concentrates for clinical use.[17,19] These concentrates could be lyophilized and stored at temperatures up to 4 °C with extended stability. Infusion of factor concentrates resulted in high circulating levels of factor VIII and factor IX without the complication of volume overload and paved the way for intensive infusion therapy for serious and life-threatening bleeding complications such as intracranial, retroperitoneal, and retropharyngeal hemorrhages and major surgery. Because they were produced from large pools of single plasma donations (>1000), initial concentrates were

Table 118-1 Development of Transfusion Therapy for Hemophilia

1832	Schönlein proposes transfusion for exsanguination[7]
1840	Lane transfuses whole blood to stop postoperative bleeding in hemophilia[8]
1905	Weil reports use of human serum to treat hemophilia[109]
1911	Addis fractionates plasma by acid method[110]
1923	Feissly uses citrated plasma in ABO-mismatched father-to-son transfusion for hemophilia[9]

nearly universally contaminated with viral pathogens such as hepatitis B and non-A, non-B hepatitis (hepatitis C).[21] Initial attempts to attenuate viral transmission using pasteurization and dry heat, instituted by manufacturers in the late 1970s and early 1980s,[22,23] were found to limit the transmission of hepatitis B. Eventually, these techniques were found to inactivate the human immunodeficiency virus (HIV).[24-26] Before the widespread application of these techniques, however, the majority of patients with severe hemophilia treated with concentrates between 1978 and 1985 were infected with HIV and hepatitis C virus. This tragic consequence of infusion therapy helped fuel the development of modern strategies to reduce the risk of viral transmission by products derived from human plasma. These strategies include (1) careful screening of potential donors for risk factors leading to infection with transfusion-transmissible infections, (2) more vigilant surveillance of the blood donor base for the appearance of new pathogens, (3) development and implementation of testing specific for markers of infectious agents, (4) purification strategies that reduce viral load in final products, and (5) physical and chemical viral inactivation methods to treat infusible products. Finally, development and refinement in techniques of molecular biology in the 1970s and 1980s resulted in the cloning of the genes for many plasma proteins, including factor VIII and factor IX.[27-29] Within the next decade, the production and licensure of biologically active recombinant factor VIII and factor IX products had become a reality.[30-33] Concentrates of these recombinant products have been shown to be effective and have not been associated with the transmission of pathogens. Further development of recombinant products centers on the removal of all human and animal proteins in the production and formulation of products to further reduce the risk of their inadvertent contamination with emerging pathogens, such as variant prions,[34,35] and newly discovered agents, such as hepatitis G virus and other transfusion transmitted viruses.[36,37] In addition, episodic supply constraints incurred in the manufacture of recombinant proteins in mammalian cell culture systems resulting in supply shortages of recombinant factor VIII[38] have led to greater interest in transgenic production of human plasma proteins compared with mammalian cell culture. With transgenic systems, raw material from which the protein of interest is purified (milk, plant tissue) can be produced in abundance.

Attenuation of Pathogens in Blood-Derived and Other Biologic Products

The development of factor VIII and factor IX concentrates in the 1960s improved the life expectancy of patients with hemophilia from approximately 11 years (before effective transfusion therapy) to nearly normal.[39] Experience with these first-generation concentrates, however, showed that they invariably transmitted the viral agents responsible for hepatitis B and hepatitis C,[21] which are associated with chronic hepatitis with attendant morbidity and mortality, including cirrhosis and hepatocellular carcinoma. Although efforts were being directed at methods to attenuate these known hepatitis viruses during the late 1970s and early 1980s,[22,23] HIV contaminated the human blood supply. More than 70% of patients in many countries and 30% to 40% of hemophilia patients worldwide were infected with HIV.[40-43] The devastating effects of both HIV and chronic hepatitis in the hemophilia patient population provided a major impetus for the improvement in viral safety of all infusible products derived from human and, in the case of porcine factor VIII, animal blood. More recently, concern about the prion agents responsible for transmissible spongiform encephalopathies such as Creutzfeldt-Jakob disease (CJD), variant CJD, and bovine spongiform encephalopathy, as well as newly identified viral agents in the blood supply,[36,37] have reinforced the need for continued surveillance and further refinements in the production of products for the treatment of hemophilia. This attention has also been focused on recombinant products because nearly all currently licensed products use added human or animal protein in fermentation or as stabilizers during purification or formulation. Table 118-2 lists agents that are potential contaminants of human

plasma. Other viruses such as cytomegalovirus and human T-lymphotropic virus type I (HTLV-1) are transmissible primarily by cellular blood products.

Although ideal, the absolute removal of infectious agents in transfusable products may be unattainable and in fact may be unnecessary because the primary goal is to make them noninfectious. Practically, this can be accomplished by reducing the levels of the contaminating agent below the level of infectivity. The most relevant agents, viruses and prions, are small and therefore difficult to separate from protein components of plasma. Some pathogens are resistant to currently used methods of inactivation. In addition, as exemplified by HIV and prions, new agents may periodically emerge in the human population by crossing species barriers. Unless detected rapidly, newly emerging agents have the potential for global dissemination, especially if they are transmitted by transfusion of contaminated blood products. Despite these limitations, the safety of infusible products derived from human or animal sources (which includes cultured mammalian cells expressing recombinant protein) can be optimized by reducing the initial viral load in the source material (human plasma, culture medium, or transgenic material). With human plasma, this is accomplished by screening to limit potentially infected donors, by removal and inactivation of infectious agents, and by prospective surveillance of all products and recipients of products that potentially may become contaminated. Progress continues in technology to reduce virus transmission; nanofiltration, an example of this, allows for more than 4 to 6 log reduction of viruses through size exclusion by filtering the solution through membranes with extremely small poor size (15-40 nm) and without denaturing plasma proteins.[44] Nonenveloped viruses such as hepatitis A and parvovirus B19, both smaller than 30 nm, can be effectively removed by nanofiltration. Benefix (Pfizer) undergoes nanofiltration.

Current discussions in the medical, health economic, and patient communities center around achieving an appropriate balance between safety and costs given that plasma-derived products on the market today are extremely safe with regard to pathogen transmission.[45]

Infusion Regimens and Dosing for Hemophilia

The mainstay of therapy for hemophilia involves the treatment of bleeding episodes with the infusion of products capable of replacing the missing factor VIII or IX. This so-called on-demand therapy is effective in staunching hemorrhage but not before tissue damage has occurred. Bleeding is especially destructive in the synovium, where a vicious cycle develops in which the initial bleed results in a proliferative inflammatory response and hypertrophy of synovial tissues that then become more susceptible to further trauma and bleeding. The result in the short term is repeated bleeds into the same joint, referred to as a "target joint," and eventually chronic joint destruction or hemophilic arthropathy. Patients with chronic arthropathy often require surgical intervention, including synovectomy, debridement, joint replacement, or even joint fusion.

With the availability of factor concentrates that allowed for the attainment of high plasma levels of factor VIII or IX, prophylactic therapy became possible. This approach was pioneered by Swedish treaters who have demonstrated that the use of prophylactic regimens,[46] wherein trough factor levels are maintained at greater than 1% of normal, reduces the incidence of arthropathy and CNS hemorrhage.[45] Greater availability of virally safe factor concentrates has allowed for the initiation of prophylactic regimens in early childhood. This "primary" form of prophylaxis has become the standard of care in developed countries. For prophylaxis, the National Hemophilia Foundation Medical and Scientific Advisory Council recommends infusion of factor VIII 25 to 50 units/kg three times a week or every other day for hemophilia A and factor IX 40 to 100 units/kg two or three times a week for hemophilia B.[47] Prophylaxis is not universally practiced, however, owing to the high cost of factor concentrates, the requirement for frequent intravenous (IV) infusion, and the need for placement of central venous catheters in some patients, especially small children, to obtain IV access. Use of central catheters is attended by the risks of catheter-induced septic and thrombotic complications.

To understand how prophylaxis is currently being instituted in the United States, a survey of hemophilia treatment centers was conducted: 62 centers responded, and 32% (or 20 centers) initiated prophylaxis on a once-weekly schedule, 21% (13 centers) on a twice-weekly schedule, and 47% on a thrice-weekly schedule.[48] This survey demonstrated the diversity in practice and deviation from the recommendation from the National Hemophilia Foundation. Alternative schedules for prophylaxis have been investigated. For example, the Canadian Hemophilia Primary Prophylaxis Study, a small, prospective, multicenter study, evaluated a tailored prophylaxis regimen in 25 patients with severe hemophilia A; patients were started at 50 units/kg once a week and were escalated to 30 units/kg twice weekly and then 25 units/kg on alternate days if one of the three situations occurred: development of a target joint, four bleeds in 3 months, or

Table 118-3 Dosing Regimens for Bleeding and Prophylaxis in Hemophilia

Site	Factor Level (%)	Dose Hemophilia A (U/kg)	Dose Hemophilia B (U/kg)	Duration of Treatment	Comments
Joint	30-70	15-35	30-70	1-3 d	Splinting, temporary splinting, no weight bearing
Life threatening (e.g., intracranial, retropharyngeal, retroperitoneal)	80-100	40-50	80-100	10-14 d	Antifibrinolytic therapy with retropharyngeal bleeds
Soft tissue	30-50	15-25	30-50	2-5 d	Higher levels can be used for compartment syndrome
Surgery	80-100	40-50	80-100	10-14 d (or shorter for minor procedures)	Significant blood loss can occur into large muscles of the lower extremity and the iliopsoas
Oral	20-50	10-25	20-50	1-2 d	Antifibrinolytic therapy
Gastrointestinal*	30-100	15-50	30-100	2-3 d	Should be evaluated for source
Genitourinary†	30-50	15-25	30-50	1-2 d	Avoid antifibrinolytic therapy
Prophylaxis‡	50	25	50	qod or 3×/wk	Steroids may be useful

five or more bleeds occurred into any one joint. This seemed to be well tolerated, resulting in 1.2 bleeds per year while maintaining good joint function; long-term follow-up of tailored prophylaxis is needed, but it may be a cost-effective and central line–sparing option.[49]

Dosing regimens for the treatment of bleeding episodes in hemophilia and for prophylactic regimens have evolved paralleling the availability of high-concentration pathogen-safe replacement products. Although no universal regimen for treatment has been established, certain trends prevail. In general, for non–life-threatening bleeding episodes, the goal of therapy is to achieve a plasma factor VIII or IX level of between 30% and 100%. For life-threatening bleeds or prophylaxis for surgical procedures, the goal is a level of 100% to be maintained by repeated bolus infusions or continuous infusion for a duration of 10 to 14 days or longer, depending on the severity of the bleed or surgical intervention.

The majority of prophylaxis regimens aim at achieving a trough factor level of approximately 1%. Prophylactic regimens can be "primary," instituted in young children to prevent bleeding episodes, especially hemarthroses that result in chronic arthropathy, or "secondary," in which limited or prolonged periods of prophylactic therapy are instituted after a serious bleed or the development of repeated bleeding into a single joint (target joint). A prospective randomized trial evaluating the safety and efficacy of a preemptive approach using once-weekly dosing before the first bleed to reduce inhibitor formation is currently in the planning stages.[50]

To prevent the development of a target joint and chronic arthropathy, many hemophilia treatment centers have recently adopted a regimen of two, three, or more infusions after a hemarthrosis. Specific dosing regimens for bleeding episodes have been developed by treaters and treatment centers. Although slight variations in indications and target plasma levels of factor VIII and factor IX among treatment centers exist, representative dosing regimens are similar and are presented in Table 118-3.[51-53]

Venous Access in Hemophilia Patients

Parents of young hemophilia patients are taught how to administer factor preparations through a butterfly needle until the patient is old enough and can be taught to self-infuse. Alternatively, visiting nurse services obtain peripheral access for some patients. Factor administration via peripheral veins can be very challenging in infants and in patients who require frequent IV therapies, such as those with inhibitors; therefore, more permanent venous access is required in some patients. Options for venous access include externally tunneled or fully implantable catheters or arteriovenous fistulas (AVFs). Hemophilia practitioners differ in their approach to venous access; one survey indicated that central venous access devices are widely used in 89% of centers and avoided in 11%.[48] Complications such as infections and thrombosis limit the life of a device and add to the morbidity of the patient. From a meta-analysis of 48 studies, the incidence of infection was 0.66 per 1000 catheter-days. A multivariate analysis of these data showed that the presence of an inhibitor was associated with an increased risk of infection; additionally, they demonstrated that the risk of infection with a fully implantable device was one-third that of an external device.[54] In one prospective study of catheter-related deep venous thrombosis (DVT) in boys with hemophilia, 69% of children had a DVT when screened and 81% at the 2-year rescreening.[55] One study of 38 hemophilia patients confirmed that AVF is feasible, with complications in 34% of the patients; this group suggests that in patients with inhibitors, AVF should be considered the first line for venous access because they frequently require long-term, daily administration of factor.[56] In deciding on access for a patient, practitioners should address the risks and benefits of each type of device on an individual basis.

TREATMENT OF HEMOPHILIA

Products Available for Treatment of Factor VIII Deficiency

Products available for the treatment of bleeding episodes or prophylaxis against bleeding in patients with hemophilia A include DDAVP (1-deamino 8-d arginine vasopressin), a vasoactive peptide that stimulates release of stored factor VIII, and infusible products containing exogenous factor VIII protein. These may be blood components, concentrates purified from blood plasma, or concentrates containing recombinant factor VIII protein.

DDAVP

The preferred product for treatment of patients with mild or moderate hemophilia A is the synthetic octapeptide DDAVP, a vasopressin analog. DDAVP causes a release of factor VIII (and von Willebrand factor [vWF]) from endothelial cells, raising plasma factor VIII by approximately threefold (range, two- to 12-fold) in patients with hemophilia in whom the disease is caused by decreased production or secretion of a functional protein or a protein that has decreased activity. To be effective, DDAVP relies on a partial quantitative deficiency of factor VIII; thus, patients with severe hemophilia will not benefit from its use if the causative mutation results in no synthesis, secretion, or a protein with no activity. In a retrospective study assessing response to a DDAVP challenge in mild or moderate hemophilia, 57% of patients with mild hemophilia had a positive response, and several who failed the initial challenge had a response after a mean of 6 years, increasing the response rate to 71% in the mild group.[57] The response to DDAVP in an individual patient is typically reproducible, and an effective response must be documented before its routine use or as prophylaxis for bleeding in surgical procedures (see box on 1-Deamino 8-D Arginine Vasopressin Trial). IV and intranasal preparations are available. The IV product has been used in a subcutaneous route of administration. The intranasal preparation more easily allows a patient to administer the compound on an as-needed basis in a home therapy regimen. The phenomenon of tachyphylaxis, the decreased effectiveness of repeated doses of the compound, occurs after several, typically three, consecutive doses.

Injectable DDAVP (Sanofi Aventis) is available in 4 μg/mL. The recommended dose is 0.3 μg/kg, mixed in 30 mL normal saline (for children <10 kg, 10 mL normal saline), infused intravenously slowly over 30 minutes. This dose can be repeated after 12 to 24 hours. DDAVP nasal spray Stimate (CSL Behring) is available in a metered-dose pump that delivers 0.1 mL (150 μg) per activation (spray). The dose is one activation for patients weighing less than 50 kg and two activations in separate nostrils for those weighing more than 50 kg. Generally, only three consecutive doses of DDAVP should be used unless otherwise advised by an experienced hemophilia treater. Because DDAVP is a vasopressin analog, there is a risk of fluid retention with its use. Changes in fluid balance can result in hyponatremia and seizures, especially when DDAVP is used in individuals on nonfluid-restricted or salt-restricted diets (e.g., elderly or very young patients or surgical patients undergoing fluid replacement with solutions with concentrations <0.9% sodium). For this reason, DDAVP is not recommended for children younger than 2 years of age. Caution is advised with the use of DDAVP in patients at risk for arterial thrombosis because there have been reports of myocardial infarction and cerebral thrombosis with its use.[58]

1-Deamino 8-D Arginine Vasopressin Trial

1. Collect citrated plasma from the patient immediately before DDAVP infusion for testing with the postinfusion blood specimen.
2. Administer DDAVP intravenously (0.3 μg/1 kg) in 25 to 50 mL normal saline.
3. Wait approximately 30 minutes after the infusion, carefully observing the patient for possible adverse side effects (increased blood pressure, facial flushing, signs or symptoms of hyponatremia).
4. Collect post-DDAVP infusion specimen in sodium citrate at 60, 120, and 240 minutes.
5. Compare the pre- and post-DDAVP FVIII:C and vWF:Ag levels to confirm a therapeutic response, threefold increase from baseline (for mild or moderate hemophilia, response is defined as twofold increase in FVIII:C levels or an absolute level above 0.31 U/mL at 1 hour).[57]

Factor VIII Concentrates

In developed countries, the current standard of care for the treatment and prevention of bleeding episodes in patients with severe hemophilia A and in patients with mild or moderate disease who do not respond to DDAVP is the infusion of recombinant human factor VIII. Recovery of recombinant factor VIII ranges from 1.5% to 2.5%/IU/kg so that dosing assumes a rise in plasma factor VIII activity of 2% for every 1 IU/kg infused. Available concentrates are optimized to enhance viral clearance during purification and undergo one or more viral inactivation steps during manufacture. Plasma-derived FVIII concentrates, treated with multiple purification and viral inactivation steps, are also available and have an excellent recent record of safety.

Intermediate- and High-Purity Plasma-Derived Concentrates

Intermediate-purity plasma-derived concentrates are prepared from cryoprecipitated plasma or fresh-frozen plasma (FFP), from which factor VIII is further purified using precipitation, gel permeation, ion exchange, or affinity chromatography, often in combination. Specific factor VIII coagulant activity in these products ranges from 2 to more than 100 IU/mg of protein, and many of the methods used also copurify significant amounts of vWF, making them useful for the treatment of some patients with von Willebrand disease (vWD; see later discussion on treatment of vWD). More highly purified plasma-derived concentrates are produced using heparin ligand or immunoaffinity purification methods and have specific activities ranging from 140 to greater than 3000 IU/mg. To stabilize the factor VIII molecule, the majority of these products are formulated by adding human albumin before lyophilization.

Highly purified recombinant factor VIII concentrates have been licensed in North America, Europe, and Japan since the early 1990s. These are either full-length or B domain–deleted molecules (the B domain is not required for activity in coagulation) that are expressed in mammalian cell culture (Chinese hamster ovary or baby hamster kidney cell lines) and are purified using immunoaffinity techniques. The development of these recombinant products was fueled primarily by concerns regarding safety of the human blood donor pool and the viral epidemics that occurred within the hemophilia population with the use of early plasma-derived products. As with highly purified plasma-derived factor VIII concentrates, the first-generation recombinant products are formulated with added albumin as a stabilizer. More recently introduced "second generation" products (Kogenate FS, Bayer, Refacto, Pfizer) have been developed that stabilize the factor VIII molecule with nonprotein excipients.[59-61] Third-generation products (Advate, Baxter, Xyntha, Pfizer) do not have human proteins or other additives in the cell culture or as a stabilizer. Recombinant production methods that do not rely on the human plasma resource theoretically should provide for unlimited supply.

Plasma/Cryoprecipitate

In communities where virally inactivated factor VIII concentrates are not available, cryoprecipitate provides an effective alternative to therapy with concentrates for hemophilia A and vWD patients. Cryoprecipitate is a small-volume product (10-15 mL) enriched in factor VIII, vWF, fibrinogen, fibronectin, and factor XIII. Dosing can be calculated assuming approximately 80 to 150 IU of factor VIII per bag of cryoprecipitate (derived from a 450-mL single whole blood donor collection unit). Thus, a typical 1750-IU dose (50% correction for a 70-kg patient) would require between 10 and 21 bags or units. The limitations of cryoprecipitate therapy are (1) lack of a viral inactivation step in manufacture of the component and (2) lack of convenience, because multiple units must be pooled into a large volume (≈70-100 mL) for infusion. FFP and whole blood provide less desirable alternatives because adequate therapy with both of these

products suffers from the limitations described for cryoprecipitate, and their use often results in intravascular volume overload. Solvent/detergent (S/D)–treated FFP product is available in some countries. ABO group–specific S/D plasma is prepared by S/D treatment (TNBP and Triton ×100) of a pool of up to 2500 donors. After removal of the solvent and detergent components, 200-mL aliquots are refrozen for infusion.

Products Available for Treatment of Factor IX Deficiency

Factor IX Concentrates

As with replacement therapy for factor VIII deficiency, intermediate- and high-purity products derived from plasma for the treatment of factor IX deficiency are available, as well as a single recombinant factor IX product. All of these concentrates also undergo at least one viral inactivation or exclusion step in manufacture. The volume of distribution of factor IX is approximately twice the plasma volume. This can be explained in part by the affinity of factor IX for type IV collagen present in the extracellular matrix.[62] Recovery of factor IX after infusion is therefore approximately 1%/IU/kg. The recovery observed with recombinant factor IX is approximately 20% lower than that observed with plasma-derived factor IX.[63] This is likely due to differences in posttranslational modifications between recombinant factor IX and plasma-derived factor IX.

Intermediate-purity factor IX products are generally purified from plasma using anion-exchange chromatography or calcium or barium precipitate adsorption. These methods select for proteins that contain highly negatively charged epitopes. The vitamin K–dependent (VKD) coagulation factors, by virtue of their gamma-carboxyglutamic acid (gla) rich domains, are such proteins; thus, these techniques copurify varying amounts of the other VKD coagulation factors, factor VII, factor X, and prothrombin with factor IX. Hence, the products are referred to as *prothrombin complex concentrates* (PCCs). The levels of vitamin K proteins in these products vary and can be obtained from the manufacturer. In addition, the PCCs are contaminated with trace amounts of activated forms of VKD factors. The presence of these activated factors is the likely explanation for thromboses that have occurred with the use of these intermediate-purity products, typically in the setting of postoperative immobility or hepatic dysfunction.[64] To minimize the risk of thrombosis with the use of PCCs, it is advisable to achieve a peak factor IX level no higher than 50%.[65] Some clinicians add small amounts of heparin to infusions of these products to prevent thrombosis, and some manufacturers have formulated PCCs with heparin or antithrombin III.

High-purity factor IX products are produced from plasma using techniques of ligand affinity or immunoaffinity chromatography and typically have specific activities greater than 150 IU/mg. Three single high-purity recombinant factor IX products have been licensed in the United States (Alphanine, Grifols; Mononine, CSL Behring; and BeneFIX, Wyeth). Because specific products have different recovery results, consulting the package insert and performing recovery studies are recommended; for example, one IU BeneFIX/kg will increase the circulating activity of factor IX by 0.8 ± 0.2 and 0.7 ± 0.3 IU/dL in adults and pediatric (younger than 15 years old) patients, respectively.[66] Also, the initial dose of BenFIX should be given under direct medical supervision because the potential for an allergic reaction is significant.[66] Thrombotic complications have not been reported with these high-purity products; some thrombotic events have been associated with continuous administration, which is not an approved method.[66] In patients with a history of allergy and inhibitors, an irreversible nephrotic syndrome has been reported during immune tolerance induction.[67]

In communities where factor IX concentrates are not available, plasma may provide a means of replacing factor IX in hemophilia B patients during bleeding episodes. Each unit of FFP derived from a 450-mL whole blood collection contains approximately 200 IU of factor IX. Replacement to therapeutic levels of factor IX with FFP is difficult because of the complication of volume overload. In some areas, S/D plasma provides a virally inactivated alternative to FFP.

Other Useful Adjuncts for Treatment of Bleeding in Hemophilia A and B

The antifibrinolytic agents tranexamic acid and ε-aminocaproic acid (EACA) (Amicar, Xanodyne Pharmaceuticals, Inc) are sometimes used in conjunction with clotting factor replacement therapy or DDAVP in the treatment of bleeding that occurs with hemophilia and other bleeding disorders. These agents interact with the lysine-binding site of plasminogen and enhance its activation. The more important effect of lysine analogs is that their occupancy of this site inhibits binding of the zymogen, plasminogen, to fibrin, which is necessary for full fibrinolytic activity. Antifibrinolytics are useful in the setting of mucosal bleeding and may substantially reduce the need for clotting factor concentrates in the setting of oral mucosal bleeding with tooth extractions. These agents are administered preoperatively and continued postoperatively until wound healing occurs. Although tranexamic acid is more potent, it is less readily absorbed when given orally. Tranexamic acid is administered at 25 mg/kg orally or 10 mg/kg intravenously preoperatively, and therapy can be continued postoperatively using oral rinses with a 5% solution. EACA is used at a dose of 100 mg/kg preoperatively followed by 100 mg/kg every 6 hours either orally or intravenously (maximum dose, 24 g/day). Dosing of EACA should be reduced in patients with renal insufficiency.

INHIBITORS OF FACTOR VIII AND FACTOR IX

A major complication in the treatment of patients with hemophilia is the development of inhibitory antibodies against the infused factors that interfere with factor activity. Rarely, antibodies may develop that do not affect activity but increase clearance of factor VIII or factor IX. The incidence of factor VIII inhibitors is approximately 30%, and inhibitors typically develop within the first 20 exposures to replacement therapy.[68,69] Well-designed prospective studies of the use of recombinant factor VIII in previously untreated patients revealed that many of these inhibitors are low titer and transient in nature.[31,32] Patients with low-titer, transient inhibitors can be managed with increased doses of factor VIII. Inhibitors to factor IX occur less frequently, with an estimated incidence of approximately 1% to 3%.[70] Patients with factor IX antibodies may have anaphylactic reactions when treated with high-purity products.[71,72]

Patients with high-titer inhibitors to either factor VIII or factor IX do not usually achieve hemostasis after factor replacement and thus present a treatment challenge. Treatment of patients who develop inhibitors involves two approaches: (1) acute treatment of bleeding episodes and (2) immune tolerance induction therapy, whereby the patient is treated frequently (often daily) with factor VIII or factor IX in an effort to suppress the production of inhibitors by the immune system (similar to allergic desensitization therapy).

Treatment of acute bleeding episodes can be accomplished by two methods. For patients with low-titer inhibitors (<5 Bethesda units [BU], a laboratory measurement of inhibitor activity), hemostasis can be accomplished with large doses of factor VIII or factor IX (e.g., as high as 200 IU/kg given at frequent intervals) in an effort to neutralize or "override" the circulating inhibitor. A neutralization approach is usually ineffective for patients with high-titer inhibitors (>5-10 BU) and is expensive because of the large amounts of factor required. These patients and patients with low-titer inhibitors who fail to respond to override therapy can be treated using products that act to "bypass" the inhibitor. The only current bypass agents include activated prothrombin complex concentrates (FEIBA, Baxter Bioscience) (aPCC), which contain factors VII, X, and prothrombin in addition to factor IX that enhance production of thrombin generation by activating the coagulation pathway at points further down

than the factor VIIIa/factor IXa step. FEIBA is used as first-line treatment of bleeding episodes in patients with inhibitors by some treaters even though the concentrate is derived from human plasma.

Recombinant activated factor VII (rFVIIa) (NovoSeven, Novo Nordisk) product was licensed in Europe and the United States with an indication for use as a bypass agent in the treatment of inhibitors in patients with hemophilia A and hemophilia B. This product has the advantage of being the only recombinant product available for the treatment of bleeding episodes in patients with inhibitors. The dose of rFVIIa is 90 μg/kg. Recombinant factor VIIa is administered every 2 hours compared with every 8 to 12 hours for PCCs or activated PCCs. Thrombosis has also been reported with the use of rFVIIa[73,74] and PCCs.

Despite the success achieved with immune tolerance induction regimens (80%-90%),[75] "bypass" agents will still be needed in patients undergoing tolerization because an interval potentially as long as 2 to 3 years exists between the time that induction is initiated and the inhibitor is suppressed. Bleeding episodes that occur before achievement of tolerance usually require treatment with one or other of the bypassing agents.

Recently, Leissinger et al[76] demonstrated in hemophilia A patients with high titer inhibitors the superiority of prophylactic thrice-weekly FEIBA (Baxter) at 85 units/kg over on-demand therapy in a prospective, randomized, crossover study with a 3-month washout between the two arms, which were each 6 months, and prevented progression of joint disease in high-titer inhibitor patients; this regimen is recommended for prophylaxis in high-titer inhibitor patients (see box Treatment of Life-Threatening Bleeding Episodes in Patients With Inhibitors Against Factor VIII or Factor IX).

Treatment of life-threatening bleeds in the context of a high-titer inhibitor represents a significant challenge. The infusion of non–factor VIII concentrates, when the inhibitor titer precludes the use of factor VIII, is less effective than treatment with factor VIII concentrates and is difficult to monitor because plasma factor VIII levels are of no value. Adjunctive therapies are frequently used in this setting to lower the titer of the antibody to allow for treatment of the patient with factor VIII concentrates. Aggressive regimens are used in which circulating antibodies are depleted using plasmapheresis or staphylococcal protein A immunoadsorption, and reduction of antibody production is attempted using immunomodulatory agents such as steroids, cyclophosphamide, and IV infusion of gamma globulin (IgG).[77-80] These strategies for acutely reducing antibody titers are also used by some hemophilia treaters at the outset of immune tolerance induction. A study sponsored by the National Heart, Lung, and Blood Institute evaluated the safety and efficacy of rituximab in reducing inhibitor levels in hemophilia A patients[81]; the study was completed, and the results are pending.

Treatment of Life-Threatening Bleeding Episodes in Patients With Inhibitors Against Factor VIII or Factor IX

Concentrates

1. Factor VIII containing concentrates in high doses (as high as 150-200 IU/kg) if inhibitor titer is low (<5-10 BU) or if neutralization can be demonstrated with high doses. High-dose continuous infusion of factor VIII (≈10 IU/kg/hour) after a high-dose bolus may be useful.
2. Recombinant factor VIIa. Dose is 90 μg/kg (or a dose up to 320 μg/kg) administered every 2 hours. Risk of thrombosis exists with this product.
3. Activated PCCs at a dose of 50 to 75 IU/kg every 8 to 12 hours. Risk of thrombosis exists with this product.

Immunomodulation

1. Antibody depletion
 a. Plasmapheresis
 b. Extracorporeal immunoadsorption of plasma (staph protein A column therapy and other methods)
2. Suppression of antibody production
 a. High-dose steroids (equivalent of prednisone 80 mg/day)
 b. Cyclophosphamide (10-15 mg/kg load and 2-3 mg/kg/day)
 c. IV immunoglobulin (1 g/kg daily for 2 days)
 d. More aggressive regimens that may include vincristine, azathioprine, cyclosporine, or interferon-γ

Conservative Measures

1. Immobilization
2. Compression
3. Local application of hemostatic agents
4. Antifibrinolytics
5. Avoid venipunctures, intramuscular injections, arterial puncture, and lumbar punctures
6. Avoid use of medications that inhibit platelet function
7. DDAVP may be effective in some patients with low titer inhibitors

VON WILLEBRAND DISEASE

von Willebrand disease is an autosomal dominant bleeding disorder first described by Erik von Willebrand in 1926, who named this bleeding diathesis *pseudohemophilia*. vWD is relatively common, with a prevalence of up to 2% of the general population.[82] The penetrance and severity of the disease vary depending on the type of vWD (type 1, 2, or 3); the specific mutation; the number of affected genes; the patient's blood type; and numerous drug, hormonal, and stress-related parameters. These factors, particularly the subtype of vWD and the patient's response to DDAVP, influence the recommended treatment for acute bleeding episodes or for prophylaxis against bleeding.

Although the disease had been described in the 1920s, the primary defect had earlier been attributed to either platelets or the vessel wall. An understanding of the missing protein in vWD and its relationship to factor VIII was not appreciated until the 1950s. Correction of the defect with transfusion of plasma, but not with platelet concentrates alone, defined the disease as one involving a missing plasma protein factor (vWF), not a platelet or vessel wall defect.[83] A correlation between vWD and factor VIII activity had previously been observed—the observation that a plasma fraction from patients lacking factor VIII (hemophilia A) could correct the defect in vWD in addition to the autosomal inheritance pattern, which helped further differentiate hemophilia A from vWD.[83] A more detailed discussion of clinical features and pathophysiology of vWD and the molecular biology of vWF can be found in Chapters 140.

Transfusion Therapy for von Willebrand Disease

The specific treatment for vWD varies with the bleeding symptoms and signs and with the subtype of vWD. Treatment is guided further by laboratory results indicating the potential success of increasing vWF with DDAVP and the clinical experience with a particular patient and his or her natural biologic family members who have vWD. When possible, attempts should be made to treat the patient without exposing him or her to plasma-derived products.

Non–Protein-Based Treatment

DDAVP is a synthetic octapeptide homolog of vasopressin that results in the release of stored vWF from Weibel Palade bodies of the endothelium (see section on treatment of hemophilia A). DDAVP is often effective for type 1 disease and may be useful in certain patients with type 2 disease. It is not appropriate for use in patients with type 3 disease in whom no stores of vWF exist. Before the use of DDAVP, a DDAVP trial should be conducted to document its efficacy in an

Table 118-4 Other Coagulation Deficiencies

Factor	Incidence	Inheritance	Chromosome	Half-Life	Target Plasma Level	Treatment Product*
I (fibrinogen)	1-2/10^6		4	2-4 days	50-100 mg/dL	Concentrates
Afibrinogen		AR				Cryoprecipitate

*Products are listed in order of viral safety.

individual patient. The trial is performed as described for hemophilia A. The phenomenon of tachyphylaxis is also observed when DDAVP is used to treat vWD. For bleeding that does not respond to DDAVP or in patients in whom a poor response is observed with DDAVP, other modalities (typically protein based) must be used.

As described for hemophilia A, the antifibrinolytic agent EACA or tranexamic acid are often administered in the setting of dental surgery to inhibit fibrinolysis. Care should be taken when these agents are administered in patients with a predisposition to thrombosis.

Estrogens upregulate vWF synthesis and may be useful especially in women. Therapy with estrogens should also help ameliorate menorrhagia in affected symptomatic patients.

Plasma-Protein–Based Therapy

Factor VIII Concentrates

Some intermediate-purity factor VIII concentrates are manufactured from plasma using methods that copurify significant amounts of vWF. Many of the products listed in Table 118-4 contain vWF. Humate-P (ZLB Behring), Alphanate (Grifols USA), and Wilate (Octapharma), which is 1:1 vWF:RCo/factor VIII, are currently licensed for the treatment of vWD. Others, including Koate-DVI (Talecris Biotherapeutics), have been tested in vitro and in vivo for their potential use in therapy for vWD.[84-86] The multimeric pattern of vWF in these concentrates varies, and no product has the pattern of multimers that is present in normal plasma.[85] Because many of these products are effective clinically, the importance of these differences in multimer pattern remains to be determined. In addition, when using multiple doses of these products, factor VIII and vWF:RCo should be monitored because there is an increased risk of thrombotic events with the accumulation of factor VIII.

von Willebrand Factor Concentrates (Plasma Derived and Recombinant)

Several chromatography-purified plasma-derived concentrates enriched in vWF have been studied by manufacturers in Europe.[87,88] Preliminary reports suggest that these are amenable to viral inactivation steps and may be effective both in vitro and in vivo.[85] To date, none of these have been developed as widely licensed products. Recombinant vWF has been successfully isolated from a number of expression systems and partially characterized, but a recombinant product for the treatment of patients has not yet been developed clinically.

Cryoprecipitate

Cryoprecipitate had been the mainstay of plasma-based therapy for bleeding in patients with vWD until the availability of virally inactivated intermediate-purity factor VIII concentrates with preserved functional vWF protein. These factor VIII concentrates are the products of choice for the treatment of bleeding in patients with types 1 and 2 vWD who are unresponsive to DDAVP and for bleeding in patients with type 3 vWD. Owing to the small potential for viral contamination of cryoprecipitate, manufacture of which does not include steps to inactivate viral pathogens, cryoprecipitate is currently indicated only when virally safe concentrates containing vWF are unavailable.

ACQUIRED FACTOR VIII AND VON WILLEBRAND FACTOR DEFICIENCY

Antibodies that inhibit the activity of factor VIII can develop in previously normal patients. Most of these patients have no underlying disease; however, factor VIII antibodies can arise in the setting of autoimmune disorders or in the postpartum period. Although approximately one-third of inhibitors disappear spontaneously, the mortality rate among affected patients is significant.

In adults, acquired vWD is a rare autoimmune disorder that can occur in association with other autoimmune disorders or lymphoproliferative disease. Antibody may interact with the epitopes on vWF required for its normal activity or result in increased clearance of antibody–vWF complexes.

In children, acquired vWD is extremely rare but has been reported in the context of Wilms tumor, hypothyroidism, and congenital heart disease and some medications; with treatment of the underlying disorder, vWF normalizes.

Treatment

Therapy for those patients with relatively high inhibitor titers (>5 BU) includes bypassing agents (FEIBA or rFVIIa) to stop bleeding

and immunosuppression to reduce inhibitor levels. Plasmapheresis or immunoadsorption can be used to reduce the circulating levels of inhibitors. Immunosuppressive agents and IV immunoglobulin (IgG) are useful adjuncts to abrogate production of the autoantibody. DDAVP can also be effective in some patients with low-titer inhibitors. Unlike inhibitors that develop with hemophilia A, exposure to factor VIII usually does not result in increased antibody titers.[89] Conservative measures to control hemorrhage should also be used in conjunction with the above, including immobilization and compression, topical or local hemostatic agents, and antifibrinolytic therapy. The use of venipunctures, intramuscular injections, and drugs with platelet inhibitory activity should be minimized or avoided.

OTHER COAGULATION PROTEIN DEFICIENCIES

Approximately 15% of inherited bleeding disorders are caused by deficiencies of coagulation factors other than factor VIII, factor IX, or vWF. Inherited deficiencies of fibrinogen and factors II, V, VII, X, XI, and XIII may result in bleeding, requiring treatment. The genes for these factors are not located on the X chromosome; thus, two gene defects are typically required for symptomatic disease. Consanguinity is frequent in affected kindreds. The characteristics of these deficiencies are presented in Table 118-4. Hereditary deficiencies of factor XII, prekallikrein, and high-molecular-weight kininogen have not been described to result in bleeding diatheses.

The mainstays of therapy for these disorders are cryoprecipitate (for fibrinogen deficiency) and plasma. In some countries, concentrates enriched in the missing protein have been available. An S/D-treated pooled plasma product is also available in some regions. Pooled S/D-treated plasma has the advantage over FFP in that it is virally inactivated but has the drawback of exposing the patient to a large number of donors (2500) with each dose.

Fibrinogen Deficiency

Bleeding disorders can result from low to absent levels of fibrinogen (hypofibrinogenemia or afibrinogenemia) or a protein with abnormal function (dysfibrinogenemia). The inheritance pattern for the former is autosomal recessive and for the latter is autosomal dominant. Dysfibrinogenemias can result in bleeding or hypercoagulability. The gene for fibrinogen is located on chromosome 4. Because fibrinogen is required for the formation of a fibrin clot, it is surprising that afibrinogenemic patients survive gestation and birth. Diagnosis is made when patients present with bleeding from the umbilical stump, intracranial hemorrhage, or mucosal bleeding. Hemarthroses can occur but are less common than observed with the hemophilias. Wound healing may be delayed. Increased incidence of fetal wastage in patients with afibrinogenemia and hypofibrinogenemia is observed, and term gestation is rarely achieved without replacement of fibrinogen.[90-92] Because the substrate for clot formation, fibrinogen, is missing or deficient, the prothrombin time (PT), activated partial thromboplastin time (aPTT), thrombin clotting time (TCT), and coagulation assays that have fibrin formation as their end points are all prolonged. Replacement of fibrinogen is accomplished with cryoprecipitate with a goal of achieving a plasma level between 50 and 100 mg/dL and at least 60 mg/dL for maintenance of pregnancy.[92] Each bag of cryoprecipitate contains approximately 200 to 300 mg of fibrinogen. The biologic half-life of fibrinogen is between 2 and 4 days. Virally inactivated fibrinogen concentrates are available in Europe, China, and Japan (Japan Green Cross, Aventis, LFB). Adverse reactions to treatment include the development of fibrinogen antibodies; allergic reactions; and, paradoxically, thrombosis.

Prothrombin Deficiency

Congenital prothrombin deficiency is a rare autosomal recessive disorder estimated to be present at a rate of 0.5 cases per million. Disease has been described with both homozygous and heterozygous defects (including compound heterozygotes). Hemorrhagic symptoms include bruising; intracranial, mucosal, and deep tissue bleeding; and menorrhagia. Hemarthroses are rare. Correlation between bleeding and prothrombin levels is poor. No reports of a prothrombinemia appear in the literature, suggesting that complete lack of the protein is incompatible with normal development. Both the PT and the aPTT time are prolonged, and the thrombin time is normal. Treatment of prothrombin deficiency includes plasma at a dose of 15 to 20 mL/kg followed by 3 mL/kg every 12 to 24 hours to achieve levels of approximately 30%. The half-life of prothrombin is approximately 3 days. Prothrombin complex concentrates contain prothrombin and other VKD factors and can be used to treat prothrombin-deficient patients who are undergoing major surgery or life-threatening bleeds. Caution should be exercised because these have been associated with thrombosis.

Factor V Deficiency

Inherited deficiency of factor V occurs in fewer than one per 1,000,000 people with an autosomal recessive inheritance pattern (homozygous or compound heterozygous), resulting in factor V levels less than 20%. Symptoms include bleeding from the umbilical stump and mucous membranes, ecchymoses, menorrhagia, postpartum bleeding, and intracranial hemorrhage. Hemarthroses can occur but are less common than with severe hemophilia. No factor V–enriched plasma concentrates are available. Because factor V is in the common pathway of coagulation, in deficiency states, both the PT and the aPTT are prolonged. Treatment of bleeding involves the infusion of plasma at 15 to 20 mL/kg with a goal of achieving levels of 20%. The half-life of factor V is approximately 36 hours. Because platelets contain stored factor V,[93] they have been used to treat bleeding. Platelet infusion may result in the production of platelet-specific antibodies.

Factor VII Deficiency

Factor VII deficiency occurs in approximately one in 500,000 people. Severe bleeding occurs with levels below 5%, and symptoms in severely affected patients are similar to those observed with severe hemophilia. Intracranial hemorrhage may occur in up to 16% of cases and in neonates after vaginal delivery. The PT is prolonged, but the aPTT and thrombin time are normal. Prothrombin complex concentrates contain factor VII and may provide a benefit over plasma because they are virally inactivated. As with the use of these products for factor VIII and factor IX inhibitors, thrombosis has been reported. Several plasma-derived factor VII concentrates have been developed and have been used to treat congenital deficiency. Recombinant activated factor VII concentrate is effective in the treatment of bleeding with a congenital factor VII deficiency.[94-97] Inhibitors to factor VIIa have developed in patients with congenital factor VII deficiency.[94]

Factor X Deficiency

Congenital deficiency of factor X is a rare condition resulting from homozygous or compound heterozygous defects in the autosomal genes for factor X located on chromosome 13. Bleeding is correlated with factor X levels, and symptoms include epistaxis, menorrhagia, hemarthrosis, intracranial hemorrhage, hematuria, and umbilical cord bleeding. Because factor X is a component of prothrombinase (the first step in the common pathway), diagnosis is suggested by both a prolonged PT and a prolonged aPTT but a normal TCT. Treatment is with plasma products (FFP or S/D-treated plasma) at approximately 10 to 15 mL/kg followed by 5 mL/kg every 24 hours with a goal of plasma factor X activity levels of 20%. No factor X–specific concentrates are available, but PCCs contain variable amounts of factor X. As with the use of PCCs for other indications,

the risk of thrombosis is increased. Currently, a Phase III, multicenter study to investigate the pharmacokinetics, safety, and efficacy of a high purity factor X (Bio Products Laboratory) is accruing patients with moderate to severe factor X deficiency.[98]

Factor XI Deficiency

Congenital factor XI deficiency (sometimes called hemophilia C) is an autosomal disorder with a recessive pattern of inheritance and is particularly common in Ashkenazi Jews in whom two specific mutations account for the approximately 8% prevalence of an abnormal factor XI gene.[95,96] The factor XI gene is located on chromosome 4. Bleeding symptoms are variable and include postsurgical or traumatic bleeding or heavy menses in women. Spontaneous hemorrhage is not typical of the disorder, and this characteristic distinguishes the disorder from hemophilia A and B. Plasma levels of factor XI do not correlate with bleeding symptoms unlike the factor levels in hemophilia A and B. The aPTT is prolonged with factor XI deficiency; PT and thrombin time are normal. Patients with factor XI deficiency are usually treated before surgical procedures with a goal of factor XI levels between 30 and 45 U/dL.[95] Plasma (FFP and S/D-treated plasma) provides the mainstay of therapy, and dosing takes into consideration the long half-life of 60 to 80 hours; however, some patients may have difficulty tolerating the large fluid volume of FFP. Although the half-life of factor XI in S/D plasma is comparable to that of FFP, decreased levels of factor XI in the product (≈30%-50%) have been reported.[97] Two virally reduced or inactivated factor XI concentrates have been developed using affinity chromatography or cation-exchange chromatography.[99] These two concentrates, licensed in France (Hemoleven, LFB Biomedicaments France) and England (FXI concentrate Bio Products Laboratory), are not available in the United States, although the factor XI concentrate from France can be obtained through compassionate use in the United States.[100] Both have been demonstrated to be effective, but there have been reports of thromboembolic complications with their use, presumably because of contaminant activated factor IX. Both products are now formulated with antithrombin and heparin, but caution is advised with their use in elderly patients and in patients with preexisting cardiovascular disease. Doses should not exceed 30 U/kg and peak factor XI should not exceed 100 U/dL.[101]

Because bleeding occurs in patients with factor XI deficiency more often in settings in which fibrinolysis is more active (oral mucosa, urinary tract), antifibrinolytic agents can be useful adjuncts in the treatment of such bleeding episodes or used as sole agents to prevent bleeding with dental procedures. Fibrin glue can provide a useful adjunct or be used solely in topical bleeding (dental extractions, circumcisions). DDAVP has been reported as useful for the prevention of surgical bleeding in factor XI deficiency.[102] The mode of effect of DDAVP is unclear but is likely due to the coexistence of mild vWF deficiency.

Factor XIII Deficiency

Factor XIII is a transglutaminase that catalyzes the cross-linking of γ-glutamyl and ε-lysyl groups of fibrin monomers, stabilizing the forming clot by decreasing its susceptibility to fibrinolysis. Inherited deficiency of factor XIII is autosomal recessive and results from defects in the genes for the two subunits of factor XIII located on chromosome 1 (B subunit) and chromosome 6 (A subunit). The majority of reported defects involve the A subunit. Umbilical bleeding in homozygotes may be observed at birth. Soft tissue bleeds, hemarthroses, excessive intracranial bleeding (relative to other coagulation deficiencies), pseudotumors, and bleeding during surgery are observed in affected patients. Surgery is also complicated by poor wound healing. Affected male patients may have oligospermia, and female patients may have recurrent miscarriages. Coagulation screening test results (PT, aPTT, and TCT) are normal. Solubility of clots is increased with factor XIII deficiency; thus, the diagnosis can be made by incubating clots in the presence of solubilizing agents such as 5 M urea or 1% to 2% chloroacetic acid. Factor XIII has a long half-life (9-15 days). Previously, FFP (2-3 mL/kg) or cryoprecipitate (1 bag/10-20 kg) were the only options for treating patients with factor XIII deficiency. However, in February 2011, the first plasma-derived factor XIII concentrate (Corifact, CSL Behring) was approved by the U.S. Food and Drug Administration for prophylaxis; this concentrate is given intravenously to maintain a trough level of 5% to 20% with the initial recommended dose being 40 IU/kg every 28 days.[103] Because of the long half-life of factor XIII, replacement can be used on a prophylactic basis (dosing every 3-4 weeks) to prevent intracranial hemorrhage and other bleeding episodes. The United Kingdom Haemophilia Centre Doctors' Organisation's current guidelines recommend that because the incidence of cerebral hemorrhage is so high, all patients with severe factor XIII deficiency should receive prophylaxis at diagnosis, and it should be considered in some moderate and mild as well.[104] Dosing with factor XIII concentrate is 10 to 75 IU/kg every 4 to 6 weeks, with lower doses for prophylaxis and higher doses for the treatment of bleeding episodes. Recombinant FXIII-A2 was found in phase I testing to be safe and potentially effective for replacement in patients with FXIII deficiency and is currently in clinical trials.[105]

OTHER PLASMA-DERIVED PROTEIN CONCENTRATES

As discussed in Chapter 117, plasma fractionation processes also allow for the isolation of plasma components other than the coagulation proteins. Immunoglobulins are isolated by a variety of techniques from the Cohn fraction II-III. α_1-Antitrypsin and antithrombin are produced from fraction IV. As with other VKD proteins, protein C may be isolated from Cohn fraction II.

Anticoagulant Proteins (Protein C and Antithrombin)

Brief mention should be made of plasma-derived concentrates enriched in protein C and antithrombin III. These products have been used for a variety of indications, but both are licensed for the treatment of congenital deficiencies that result in thrombosis. Protein C concentrate has also been used in the treatment of purpura fulminans with meningococcemia. Antithrombin in combination with defibrotide has been used for the successful treatment of venoocclusive disease in patients who develop this complication after undergoing bone marrow transplantation,[106] heparin resistance in patients undergoing cardiopulmonary bypass, and sepsis. Additionally, antithrombin has been used in patients with acute lymphoblastic leukemia who are receiving asparaginase. Early studies showed some efficacy in using activated protein C to treat sepsis.[107] However, a recent update of a Cochrane review reported that in five randomized controlled trials, including 5101 patients, activated protein C did not decrease the risk of death and was associated with an increased risk of bleeding.[108] Its utility for other indications is not yet known.

Immunoglobulins

The use of immunoglobulins (both IV and hyperimmune products) for a variety of diseases is discussed elsewhere in this book.

α_1-Protease Inhibitor (Antitrypsin)

α1-Protease inhibitor (or antitrypsin) concentrates (Prolastin, Bayer Healthcare LLC; Aralast, Baxter Biosciences; Zemaira, ZLB-Behring) are available for the prophylactic treatment of people with congenital deficiency of α_1-antitrypsin. α_1-Antitrypsin inhibits neutrophil elastase, which is thought to be responsible for the alveolar damage resulting in emphysema. These replacement products, administered

intravenously, are presumed to act to delay the progression of congenital emphysema associated with this protease inhibitor deficiency.

FUTURE DIRECTIONS

Virally safe plasma-derived concentrates have been developed that are enriched in a variety of coagulation and other proteins. Initially, refinements in techniques of plasma fractionation formed the basis for the development of these concentrates as an improvement over the use of blood component therapy (whole blood, plasma, and cryoprecipitate). Plasma-derived protein concentrates were first developed for the treatment of the more common hemophilias A and B. Subsequent refinements were made to reduce and then eliminate the transmission of viral and other pathogens present in the human plasma pool while increasing product purity. Techniques in molecular biology and heterologous expression of mammalian proteins have allowed for the production of some proteins, most notably factor VIII and factor IX, without reliance on the limited plasma resource. These plasma-derived and recombinant concentrates have supplanted the use of plasma or cryoprecipitate for the treatment of some congenital and acquired deficiencies of soluble plasma factors and have decreased or eliminated the attendant risks of allergic reactions, volume overload, and pathogen transmission. For patients on home infusion regimens, protein concentrates also have the benefit of increasing patient convenience because infusion volumes are small relative to blood component therapy. Although the development of high-purity, virally safe concentrates to treat other plasma protein deficiencies that are currently treated with blood components is technically feasible, such development is limited by the very small numbers of patients with these disorders. In the future, the development of products produced in transgenic animals holds the promise of producing large quantities of recombinant proteins, thus making available more of these lifesaving products for use clinically.

CHAPTER 119

HEMAPHERESIS

Diarmaid Ó Donghaile and Harvey G. Klein

Bloodletting is an ancient therapy, fashionable, albeit unproved, and practiced well into the 19th century. About the time that scientific skepticism began to temper the widespread use of therapeutic phlebotomy, a new technique for blood removal, apheresis, appeared in the research laboratory. The term *apheresis*, derived from a Greek verb meaning "to take away or withdraw," was coined to describe removal of one component of blood with return of the remaining components to the donor. Like phlebotomy, apheresis was used first to treat patients but later became more important for collecting blood components for transfusion. Increasingly, apheresis techniques are used to collect cell populations from the peripheral blood of healthy donors and patients for purposes of hematopoietic stem/progenitor cell (HPC) transplantation and immune cell therapies. Annually in the United States, more than 50,000 units of peripheral blood stem cells (PBSCs) and therapeutic cellular therapy products are collected at hospital and blood center apheresis facilities.[1]

PRINCIPLES OF APHERESIS

The principal objective of apheresis is efficient removal of some circulating blood component, either cells (cytapheresis) or some plasma solute (plasmapheresis). For most disorders, the treatment goal is to deplete the circulating cell or substance directly responsible for the disease process. Apheresis can also mobilize cells and plasma components from tissue depots. For example, lymphocytes may be mobilized from the spleen and lymph nodes of some patients with chronic lymphocytic leukemia (CLL), and low-density lipoproteins (LDLs) can be removed from tissue stores in patients with familial hypercholesterolemia. Apheresis also appears to mobilize $CD34^+$ cells from extravascular depots in peripheral blood stem/progenitor cell (PBSC) donors, resulting in collection of more than twice as many $CD34^+$ cells than estimated based on pre-apheresis peripheral blood cell counts (Fig. 119-1). Apheresis may have other, less obvious effects. Lymphocyte depletion may modify immune responsiveness in some disease states, possibly by disturbing the control mechanisms of cellular immune regulation. Plasmapheresis enhances splenic clearance of immune complexes in certain autoimmune disorders. When therapeutic effect is judged by clinical improvement rather than by efficiency of solute removal, apheresis is more often a helpful adjunct than a form of first-line therapy.

Several mathematic models formulated for different clinical conditions describe the kinetics of apheresis. Removal of most blood constituents follows a logarithmic curve (Fig. 119-2). This model assumes that the substance removed is neither synthesized nor degraded substantially during the procedure, remains within the intravascular compartment, and mixes instantaneously and completely with any plasma replacement solution. When the goal of plasmapheresis is to supply a deficient substance, for example, the cleavase ADAMTS13 in the treatment of thrombotic thrombocytopenic purpura (TTP), replacement follows logarithmic kinetics similar to those developed for solute removal. From Fig. 119-2, it is evident that removal of 1.5 to 2.0 volumes will reduce an intravascular substance by approximately 80% and that processing larger volumes results in little additional gain. Specific cell removal with centrifugal automated cell separators depends on the number of cells available, the volume of blood processed, the efficiency of the particular instrument, and the separation characteristics of the different cells. Most commercially available instruments remove platelets and lymphocytes extremely efficiently. Granulocytes and other mononuclear cells, including HPCs from peripheral blood, cannot be cleanly separated from other cells by standard centrifugal apheresis equipment (Fig. 119-3). Optimal harvesting of these cells requires special techniques such as stimulating the donor with corticosteroids or cytokines and adding sedimenting agents to enhance cell separation.

Whereas the model above accurately estimates removal of cells and large proteins such as fibrinogen and immunoglobulin M (IgM), removal of smaller solutes such as IgG and albumin-bound drugs is less efficient. Transfer of these moieties from the extravascular to the intravascular compartment depends both on diffusion along a concentration gradient and on active transport. The rate of clearance can be calculated using diffusion coefficients, sieving coefficients, and lymphatic flow rate, although in practice this degree of accuracy is rarely necessary.

TECHNOLOGY AND TECHNIQUES

The plasmapheresis technique that originated in the animal laboratory required manual resuspension of red blood cells (RBCs) and posed a substantial risk of microbial contamination of the components being reinfused. With the introduction of sterile, disposable, interconnected plastic blood bags, plasmapheresis became relatively safe and easy. However, manual apheresis proved too inefficient and labor intensive for collecting large component volumes and raised concerns that the separated units of RBCs might be reinfused accidentally into the wrong donor or patient. The introduction of automated online blood cell separators solved these problems. Automated apheresis instruments use microprocessor technology to draw and anticoagulate blood, separate components either by centrifugation or by filtration, collect the desired component, and recombine the remaining components for return to the patient or donor. The equipment contains disposable plastic software in the blood path and uses anticoagulants containing citrate or combinations of citrate and heparin that do not result in clinical anticoagulation of the patient or donor. Most instruments function well at blood flow rates of 30 to 80 mL/min and can operate from peripheral venous access or from a variety of multilumen central venous catheters. Newer therapeutic apheresis devices are smaller and more automated, allowing for implementation of more safety functions and improved portability.

Because the ideal method for treating disorders mediated by abnormal plasma components is to remove the offending substance selectively, a variety of online filtration and column adsorption techniques have been introduced or proposed. Ligands bound to a column matrix may be relatively nonspecific chemical sorbents, such as charcoal or heparin, or specific ligands, such as monoclonal antibodies and recombinant protein antigens. Two such columns are commercially available: one using staphylococcal protein A and the other using negatively charged dextran sulfate cellulose beads. Staphylococcal protein A has high affinity for the Fc portion of IgG1, IgG2, and IgG4 and for immune complexes containing these IgG subtypes. This column is approved for use in therapeutic apheresis procedures for patients with chronic immune thrombocytopenia and selected adult

Cell type	Blood concentration			Cell content			Apparent volume of distribution	
	Initial	End	% change*	Blood†	Product‡	Fraction§	Liters	No. of blood volumes

* Percentage change, end vs. iniial

† Estimated initial content in peripheral blood

‡ Total product content

§ Total product content divided by estimated initial content in peripheral blood. I, liters. CD34 cell concentration in 10^9/L, CD34 cell content x 10^8 cells.

Figure 119-1 TWENTY HEALTHY MOBILIZED DONORS UNDERWENT EITHER A SINGLE LARGE VOLUME LEUKAPHERESIS PROCEDURE OF 25 L OR TWO CONSECUTIVE-DAY SMALLER VOLUME PROCEDURES OF 15 L EACH. In both study groups, more than twice as many CD34 cells were collected than the estimated total content of these cells in the peripheral blood before apheresis, providing evidence for the existence of a large extravascular pool of peripheral blood stem cells (PBSCs), which becomes accessible to collection by leukapheresis. *(Modified from Bolan CD, Carter CS, Wesley RA, et al: Prospective evaluation of cell kinetics, yields and donor experiences during a single large-volume apheresis versus two smaller volume consecutive day collections of allogeneic peripheral blood stem cells,* Br J Hematol *120:801, 2003, by permission of the authors.)*

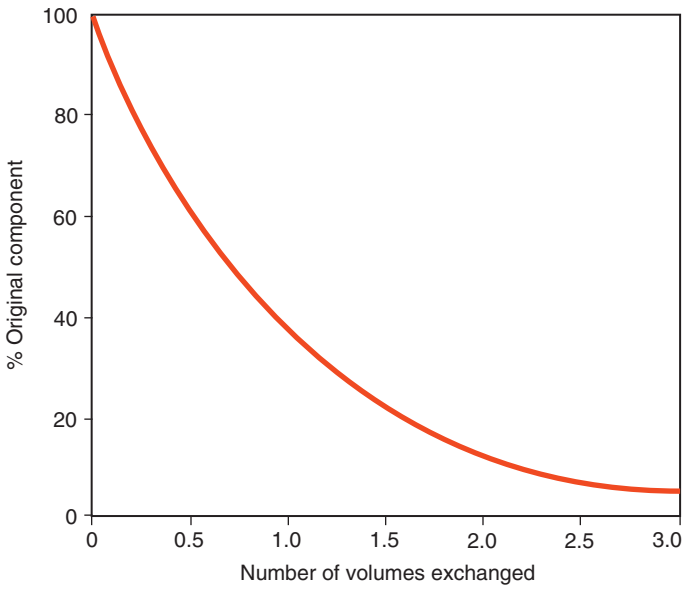

Figure 119-2 RELATIONSHIP BETWEEN VOLUMES REMOVED BY APHERESIS AND PERCENTAGE OF THE TARGET COMPONENT REMAINING. The relation is valid for blood volumes during red blood cell exchange or for plasma volumes during plasmapheresis if the target solute remains primarily within the intravascular compartment.

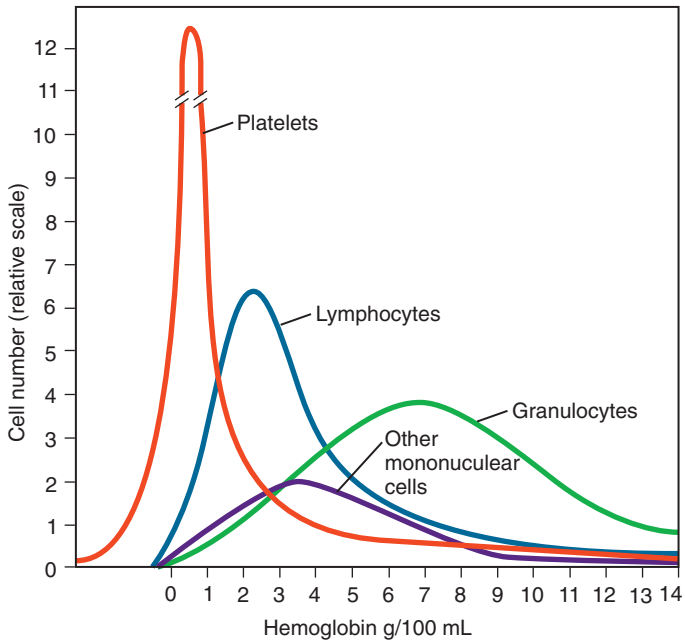

Figure 119-3 SCHEMATIC DISTRIBUTION OF CELLS AT THE COLLECTION PORT OF A CENTRIFUGAL CELL SEPARATOR. The number and percentage of each cell type collected can be varied by adjusting the site of collection along the interface or by changing centrifugal force, blood flow rate, or rate of cell removal.

patients with rheumatoid arthritis. The dextran sulfate cellulose columns selectively remove LDL, very-low-density lipoprotein, and lipoprotein (LP^a), and have proved effective in managing patients with homozygous hypercholesterolemia who have not responded to diet and cholesterol-lowering drug therapy (Fig. 119-4). A similar technique, heparin-induced extracorporeal lipoprotein precipitation, uses low pH and negatively charged heparin to precipitate lipoproteins and remove the precipitate by filtration online (H.E.L.P. Plasmat Futura, Braun Medical). Apheresis technology has also been adapted for extracorporeal phototherapy of patient leukocytes (photopheresis) to treat cutaneous T-cell lymphoma and to modulate the pathologic immune response in graft-versus-host disease (GVHD), solid organ transplant, and autoimmune diseases (see later discussion).

THERAPEUTIC CYTAPHERESIS

Common indications for therapeutic cell removal are listed in Table 119-1. Most of these procedures entail simple apheresis of the patient's peripheral blood with diversion for discarding the affected RBC, white blood cell (WBC), or platelet fraction. Special apheresis technologies have been approved, such as photopheresis devices, that divert a cell fraction that is photochemically treated in the extracorporeal circuit and returned to the patient's circulation, and apheresis immunoabsorption columns, which selectively remove immunoglobulins in the plasma by binding to a solid matrix.

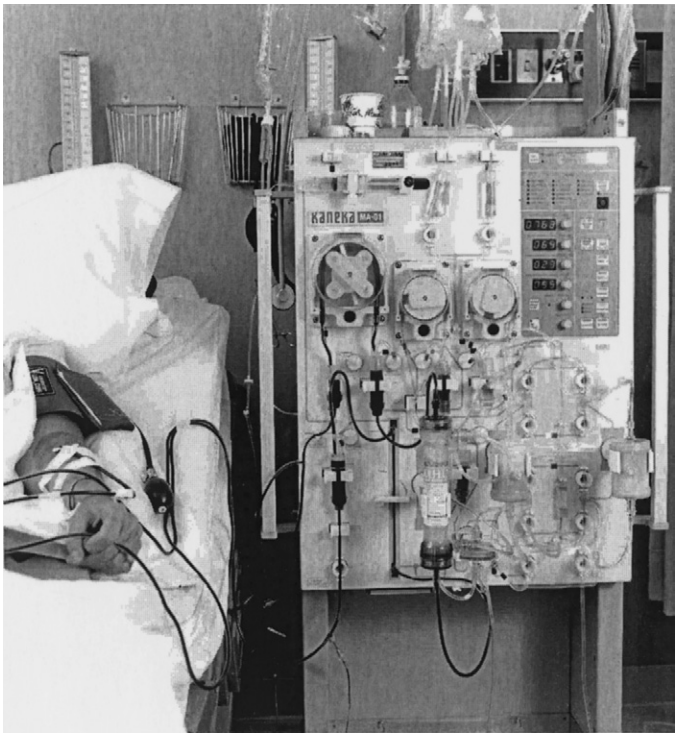

Figure 119-4 TWO-STAGE THERAPEUTIC PLASMAPHERESIS. Plasma is separated from cells by filtration and then passed through parallel adsorption columns to remove low-density lipoproteins from a patient with homozygous familial hypercholesterolemia.

Table 119-1 Common Indications for Therapeutic Cytapheresis

Erythrocytapheresis
Acute complications of sickle cell disease
Prophylaxis for recurrent stroke
Frequent severe pain crises
Hyperparasitemia (malaria, babesiosis)
Hemochromatosis
Leukapheresis
Leukemia with hyperleukocytosis syndrome
Cutaneous T-cell lymphoma (photopheresis)
Peripheral blood stem cell collection
Plateletpheresis
Symptomatic thrombocytosis

Erythrocytapheresis

Red blood cell exchange (erythrocytapheresis) is used most often to manage or prevent the acute vasoocclusive complications of sickle cell disease. Compared with manual exchange transfusion, mechanical cell separators offer the advantages of speed and ease and reduce the risks of rapid blood volume alteration and increased blood viscosity that may occur with simple transfusion. Automated procedures can be performed with all centrifugal instruments and programmed procedures allow accurate prediction of target hemoglobin concentration and percent hemoglobin A (HbA) at the conclusion of the procedure. A single volume exchange will remove about two-thirds of the circulating cells. Sickle cell anemia occurs in individuals who are homozygous for a single mutation in codon 6 of the β-globin gene, resulting in substitution of a single amino acid. Although the defect appears simple, the pathophysiology of the vasoocclusive crises is complex, involving hemoglobin polymerization, change in cell shape, adhesion to endothelial cells, dysregulated nitric oxide homeostasis, and release of free hemoglobin and inflammatory cytokines.[2] Clinical manifestations vary from patient to patient. The rationale behind exchange transfusion involves improving tissue oxygenation, reducing hemolysis, and preventing microvascular sickling by diluting the patient's abnormal RBCs, simultaneously correcting anemia and favorably altering whole blood viscosity and rheology. No clinical data support a single optimal level of HbA; however, as few as 30% of transfused cells markedly decrease blood viscosity. At mixtures of 50% or greater, resistance to membrane filterability approaches normal. In nonemergency situations, such levels can often be achieved with a simple transfusion regimen. For simple and exchange transfusions, raising the level of Hb A to between 60% and 70% while lowering the level of Hb S to 30% is generally efficacious, although even higher levels of HbA may be required to treat an ongoing crisis. Clinical indications for exchange transfusion in patients with sickle cell anemia remain controversial, with limited controlled study data available. Simple transfusion has been shown to improve renal concentrating ability and splenic function in young sickle cell patients; exchange transfusion improves exercise tolerance and reverses the periodic oscillations in cutaneous blood flow associated with this disease. Such observations have encouraged the use of exchange transfusion for acute complications of sickle cell disease such as acute chest syndrome, priapism, cerebrovascular accident, and hepatic and retinal infarction. Exchange transfusion for sickle cell patients has also been used for prophylaxis during pregnancy and before surgery, although prophylactic transfusion in these settings is controversial. The only randomized trial of transfusion during pregnancy has shown that prophylactic transfusion sufficient to reduce the incidence of painful crises did not reduce other maternal morbidity or perinatal mortality. The risk of intrauterine growth restriction may be reduced by prophylactic exchange transfusion; however, the study is limited by the retrospective observational nature of the data.[3] In a randomized study of sickle cell disease patients undergoing surgery, a conservative simple transfusion regimen (to increase the Hb level to 10 g/dL) was as effective as an aggressive regimen (to lower the Hb S level to <30%) with respect to perioperative non–transfusion-related complications. The patients in the aggressive regimen group received twice as many units of blood, had a proportionally increased RBC alloimmunization rate, and had more hemolytic transfusion reactions. The results of this and other studies suggest that if prophylactic preoperative exchange transfusion is used, it should be limited to patients undergoing high-risk procedures in whom simple transfusion could not effectively raise the Hb A level to 70% or higher.

Transfusion prophylaxis is now clearly indicated for children at high risk for stroke. A randomized controlled study demonstrated a risk reduction of 90% in the patients who were maintained at levels of 30% or less HbS by simple or exchange transfusion. This result confirms earlier experience and indicates that in this group of children with sickle cell anemia, transfusion therapy should begin before the first event and continue indefinitely. A second trial then addressed whether transfusion could be safely discontinued because of the cumulative long-term risks of iron overload from simple transfusion and RBC alloimmunization. After 10 months of randomization, half of the patients who discontinued transfusion had developed abnormalities, including reversion to abnormal transcranial Doppler findings and a small number of strokes, necessitating and early conclusion to the trial. Furthermore, long-term erythrocytapheresis may be preferable for patients at high risk for stroke who have developed iron overload to levels associated with organ damage. Exchange transfusion, although relatively safe and convenient, carries all the complications of RBC transfusion. Patients are exposed to a large number of donors and are at a small but significant risk of contracting hepatitis and other bloodborne infections. As many as 33% of all patients develop alloantibodies, and life-threatening delayed hemolytic transfusion reactions have been reported. In addition, an immunohematologic study of multiply transfused sickle cell patients shows that 85% of heavily transfused patients are alloimmunized to human leukocyte antigens (HLAs), platelet-specific antigens, or both. Most

centers avoid inducing nonhemolytic transfusion reactions and HLA alloimmunization by using leukocyte-depleted RBCs. Extended RBC phenotyping at diagnosis and provision of phenotypically matched blood, when practical, can reduce the risk of RBC alloimmunization and associated hemolytic transfusion reactions. Despite the removal of RBCs during exchange, most patients remain in positive iron balance, although iron accumulation is slow and chelation is rarely required to prevent transfusional hemosiderosis.

Other indications for RBC exchange are rare. The procedure has been used for patients with overwhelming RBC parasitic infections, such as severe and complicated malaria and babesiosis. In malaria, exchange transfusion may have at least three beneficial effects. An automated exchange rapidly decreases the concentration of circulating parasites while improving the rheologic properties of the blood by replacing the infected RBCs. The exchange may also reduce levels of proinflammatory cytokines and may help sustain life until conventional therapy and natural immunity take effect. Although the efficacy of this therapy has not been evaluated by controlled trials, prospective studies and review of published cases suggest the use of erythrocytapheresis for parasitemia greater than 10% to 15% or even less in selected patients such as those with cerebral malaria or pulmonary edema. Case reports document RBC exchange in such diverse conditions as carbon monoxide poisoning and G6PD-deficient hemolysis.

Automated RBC removal with volume replacement (isovolemic hemodilution) can be performed rapidly and safely in polycythemic subjects. This maneuver should be reserved for polycythemic patients with an urgent clinical indication to lower the hematocrit (e.g., evolving thrombotic stroke) for which standard single-unit manual phlebotomy might be inadvisably slow. Automated double RBC apheresis technology has more recently been used to treat individuals with hereditary hemochromatosis. This procedure removes excess iron more rapidly than manual phlebotomy and may be more tolerable to patients because of the lower frequency of maintenance procedures required (Fig. 119-5). Emerging data from patients randomized to simple phlebotomy versus therapeutic erythrocytapheresis indicates a potential 74% reduction in the total number of procedures in the latter group.[4]

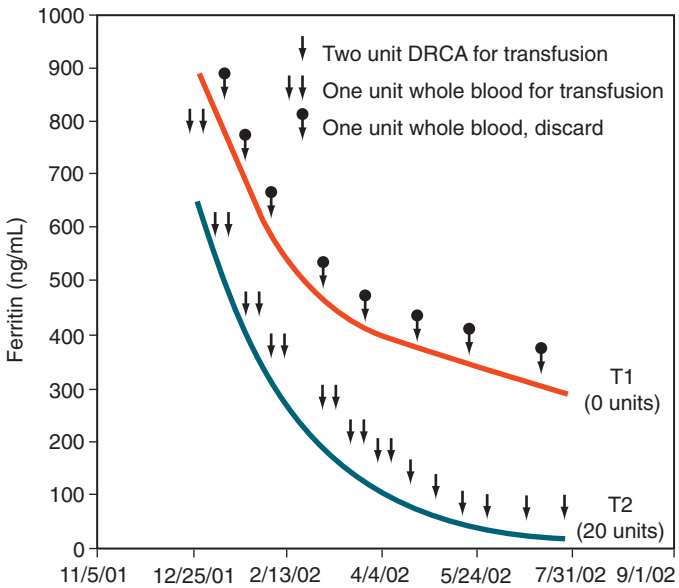

Figure 119-5 ONE TWIN WAS TREATED WITH MANUAL PHLEBOTOMY (T1) AND THE OTHER WITH DOUBLE RED BLOOD CELL APHERESIS (DRCA) (T2). In the same time period, ferritin levels declined more rapidly and to lower levels in the twin treated with double red blood cell apheresis. *(Unpublished data from Bolan CD, Leitman SF, with permission of the authors.)*

Leukapheresis

Therapeutic leukapheresis has been used most successfully to help manage patients with acute leukemia and extremely high WBC numbers, so-called acute hyperleukocytic leukemia (AHL). When the fractional volume of leukocytes (leukocrit) exceeds 20%, blood viscosity increases and leukocytes can interfere with pulmonary and cerebral blood flow and compete with tissue for oxygen in the microcirculation. Investigations of the expression and function of adhesion receptors in leukemic cells and the role of adhesion molecules in leukocyte-induced acute lung injury in sepsis suggest that the pathophysiology of leukostasis in AHL may also be related to interactions between leukemic blasts, platelets, and endothelial cells mediated by locally released adhesion molecules. A single-volume leukapheresis procedure generally reduces the WBC count by 20% to 50%, depending on the differing sedimentation characteristics of the specific blast cell population. Ordinarily, leukapheresis is initiated in a patient with acute myeloid leukemia (AML) or in the accelerated phases of chronic myeloid leukemia (CML) when the blast count exceeds 100,000/mm^3 or when rapidly rising blast counts are higher than 50,000/mm^3, especially when evidence of central nervous system or pulmonary symptoms appears. The threshold for initiation of leukapheresis in patients with acute lymphocytic leukemia (ALL) is generally higher (WBC count >200,000/mm^3). Leukostatic syndromes do not occur when concentrations of well-differentiated lymphocytes exceed even several million/mm^3.

Although leukapheresis may be effective in numerically reducing the number of circulating blasts, the evidence for clinical benefit is less certain. The data are controversial because of a lack of a randomized controlled trial and reliance on retrospective studies. Leukapheresis may reduce early death (ED) rates but does not improve the overall survival of patients with AML.[5] Trials reporting reduction in ED need to be interpreted with caution because one retrospective cohort study associated leukapheresis with a poorer outcome attributed to a delay in commencing chemotherapy.[6] Therefore, leukapheresis should not delay other immediate measures for treatment of patients with AHL include infusion of intravenous (IV) fluids, administration of hydroxyurea, and uricosuric medication with urinary alkalization, and correction of coagulopathy and thrombocytopenia.

Mechanical cytoreduction for managing other leukemic processes has limited value. Although repeated leukapheresis has adequately reduced the WBC count in a series of patients with CML, the median patient survival rate was not significantly different from that of similar patients treated with conventional chemotherapy. Chronic leukapheresis can provide acceptable control of the peripheral WBC count in clinical situations such as pregnancy, when cytotoxic agents may best be avoided, but cytoreduction alone does not appear to alter the course of CML. In a limited series of patients leukapheresis in combination with interferon has successfully controlled the disease until therapy with tyrosine kinase inhibitors could begin after delivery.[7] Some studies of patients with CLL suggested short-term clinical benefit, but long-term support of patients when the disease is refractory to chemotherapy does not appear to prolong life.

Lymphocyte removal by apheresis has also been used to modify immune responsiveness in patients with autoimmune diseases and to enhance solid organ allograft survival and reverse solid organ graft rejection, but evidence of clinical efficacy in these situations is sparse. Removal of large numbers of lymphocytes over a period of a few weeks can suppress peripheral lymphocyte counts in patients with rheumatoid arthritis for up to 1 year and can alter skin test reactivity and lymphocyte mitogen responsiveness to a variety of stimulants. Selected patients experience a modest but significant reduction in disease activity; however, the subset of patients who may derive substantial benefit from this therapy is difficult to identify. Because leukocytes are a major source of inflammatory cytokines implicated in the pathogenesis of inflammatory bowel diseases (IBD), nonpharmacologic methods for selective leukoreduction have been developed to treat these chronic, relapsing, lifelong disorders. Although IBD respond to a variety of drug regimens, leukapheresis may have a role

as a "steroid-sparing" agent for patients who develop toxicity from long-term steroid use. Cellsorba removes leukocytes by extracorporeal filtration. Granulocyte-monocyte apheresis (Adacolumn) selectively adsorbs cells through columns filled with cellulose beads.[8] Clinical trials using Adacolumn technology have promising results in the treatment of ulcerative colitis, with remission rates in excess of 70% compared with conventional medical therapy. The studies are limited, however, by high risk of bias and inclusion of predominantly Japanese patients, limiting how results may be applied to western populations with different genetic and environmental factors.[9] Because the optimum course of therapy is yet to be defined, recent trials have investigated the safety and efficacy from weekly to procedures on a daily basis.[10]

Photopheresis, although not strictly a "cell removal" procedure, involves an automated extracorporeal photochemotherapy (ECP) treatment that includes leukapheresis, extracorporeal photoactivation with a light-sensitizing agent, 8-methoxypsoralen (8-MOP) and ex vivo ultraviolet A irradiation, and reinfusion of the leukocyte fraction (Fig. 119-6). The light-sensitizing agent is delivered directly to the extracorporeal leukocyte fraction, which may reduce the adverse effects such as nausea and vomiting associated with oral administration. The mechanism of action of photopheresis is unclear but may involve induction of apoptosis in pathogenic T lymphocytes and induction of a dendritic cell–mediated cytotoxic T-cell response. This therapy has minimal toxicity and is highly effective in the treatment of patients with advanced cutaneous T-cell lymphoma. Patients who present with the erythrodermic form and circulating malignant cells have the best clinical response. Photopheresis is typically performed once or twice a month, with symptomatic patients with higher circulating tumor burden benefiting from a more intense regimen.[11] Other disorders reported to respond to photopheresis therapy include cardiac and other solid organ graft rejection, and GVHD after stem cell transplantation in patients who do not respond to standard immunosuppressive therapy. Patients with chronic extensive GVHD should be considered for treatment, with best responses observed in cutaneous, mucous membrane and liver forms of the disease. Treatment commonly involves a trial of two ECP treatments on consecutive days every 2 weeks followed by an evaluation at 3 months. A response may facilitate a reduction in immunosuppression ("steroid sparing") with continued photopheresis.[11]

Acute rejection in cardiac transplantation occurs in 25% of recipients in the first year. In 30% to 50% of cases, acute rejection is T cell mediated. Prospective studies have shown benefit of photopheresis in prevention of rejection.[12] In the case of lung transplant, utility has only been studied retrospectively. Chronic rejection is manifest as bronchiolitis obliterans syndrome, presenting as progressive dyspnea and airflow limitation. ECP is associated with a reduction in rate of decline in lung function with progressive disease.[13] The acute adverse effects of photopheresis include skin erythema, low-grade fever, and transient hypotension. Anemia caused by incomplete reinfusion of RBCs may occur in patients undergoing long-term photopheresis.

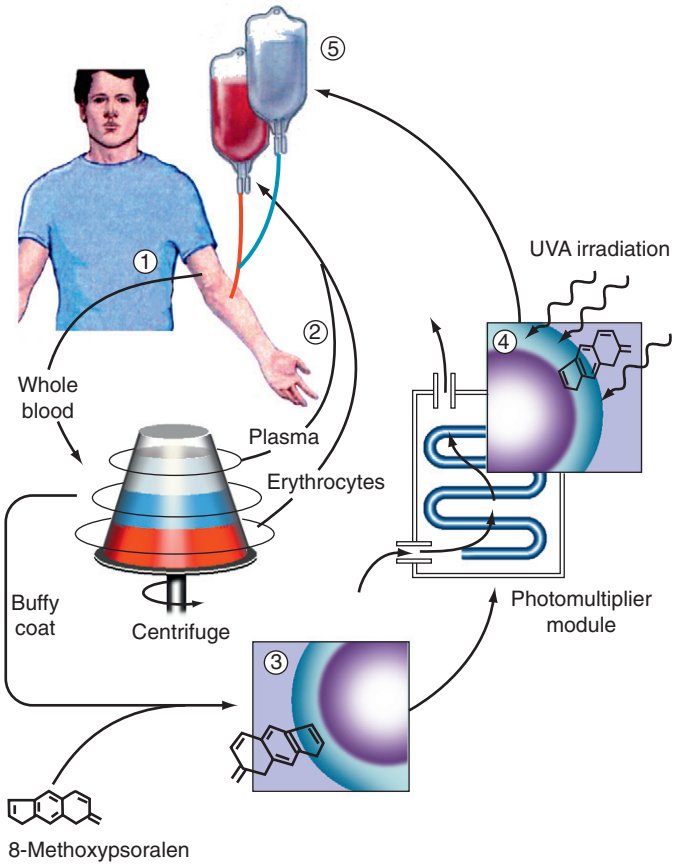

Figure 119-6 OVERVIEW OF A PHOTOPHERESIS PROCEDURE. (1) Vascular access is achieved by placement of a peripheral intravenous line or through a temporary central venous catheter. Whole blood is withdrawn from the patient, mixed with an anticoagulant solution, and pumped to a centrifuge, where it is separated into plasma, red blood cell, and mononuclear cell (buffy coat) fractions by elutriation. (2) After the collection of each mononuclear cell fraction, the uncollected red blood cells and plasma are pumped from the plasma/return bag through a blood filter and returned to the patient. (3) The mononuclear cell fractions are mixed with 8-methoxypsoralen and then (4) pumped through a sterile cassette surrounded by ultraviolet A (UVA) bulbs, resulting in a controlled rate and amount of UVA exposure. (5) The treated cell fraction is filtered and returned to the patient.

Plateletpheresis

Therapeutic plateletpheresis is generally reserved for patients with myeloproliferative disorders and hemorrhage or thrombosis associated with an increase in circulating platelets. Many centers consider using plateletpheresis when the patient's peripheral platelet count is greater than $10^6/mm^3$, although no consistent relationship between the level of platelet elevation and the occurrence of symptoms has been found and no generally accepted assay of platelet dysfunction predicts which patients are at risk. A single cytapheresis procedure can lower the platelet count by 30% to 50%. Plateletpheresis can have dramatic effects for selected patients such as those with evolving digital gangrene. Attempts to maintain thrombocythemic patients at normal platelet counts by cytapheresis alone have not been successful; more practical long-term chemotherapy should be instituted concurrently. Because most patients with thrombocytosis do not develop symptoms, including patients with myeloproliferative disorders, prophylactic plateletpheresis is unwarranted regardless of the platelet count. Pregnant patients with essential thrombocythemia may be at increased risk of first trimester abortion, however. Periodic plateletpheresis has been used in limited series, with weekly procedures necessary until delivery.

THERAPEUTIC PLASMAPHERESIS

Common clinical indications for therapeutic plasmapheresis are outlined in Table 119-2. Most procedures are performed for treatment of immunologic and hematologic disorders. A course of plasmapheresis generally consists of five to seven exchanges of 1 to 1.5 plasma volumes each, either daily or with an interval of 1 to 2 days between procedures, although the course of therapy varies depending on the specific disease indication and rate and duration of response.

Several expert committees have published practice guidelines for using plasmapheresis in a wide variety of disease states.[14,15] Some of the least controversial indications for plasmapheresis are supported by small series of uncontrolled cases that rely on some objective clinical or laboratory measurement of patient improvement.

Table 119-2 Common Indications for Therapeutic Plasmapheresis

Hematologic Diseases (Including Blood Cell–Specific Autoimmune Diseases)
Thrombotic thrombocytopenic purpura
Idiopathic thrombocytopenic purpura (immunoabsorption)
Hyperviscosity
Posttransfusion purpura
Cold agglutinin syndrome
ABO-mismatched marrow transplant (recipient)
Autoimmune Diseases
Cryoglobulinemia
Rheumatoid arthritis (immunoadsorption, lymphoplasmapheresis)
Myasthenia gravis
Goodpasture syndrome
Guillain-Barré syndrome
Chronic inflammatory demyelinating polyneuropathy
Metabolic Diseases
Homozygous familial hypercholesterolemia (selective adsorption)
Refsum disease
Other
Drug overdose and poisoning

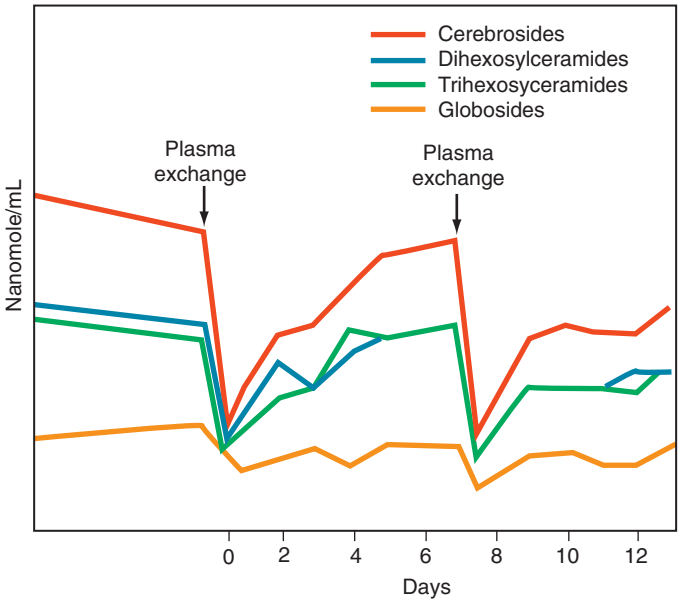

Figure 119-7 PLASMA EXCHANGE TO REMOVE PLASMA NEUTRAL GLYCOLIPIDS IN A PATIENT WITH FABRY DISEASE. The plasma lipid recovery curve appears to be biphasic, reflecting initial reequilibration from tissue stores and subsequent new synthesis of that glycolipid.

Hematologic Indications

Two of the most common indications for plasmapheresis are treatment of TTP and treatment of clinical syndromes associated with paraproteinemias. Plasma exchange with fresh-frozen plasma (FFP) replacement has been estimated to improve survival rates of patients with TTP from 10% to more than 75%. Comprehensive reviews of the clinical and laboratory evaluation and treatment of patients with suspected TTP, including management with plasma exchange therapy, have been published.[16] Treatment usually involves daily single-volume plasma exchange with both frequency and duration of treatment guided by clinical response and continued until the platelet count is above 150,000/μL and lactate dehydrogenase is near normal for 2 to 3 consecutive days. The persistence of schistocytes on the peripheral blood smear does not preclude weaning or discontinuation of treatment. Typically, patients should respond within 2 or 3 days of beginning treatment. In acutely unwell patients, escalating the intensity of plasma exchange to twice daily may be necessary.[17] Despite initial reports of improved response rates in certain patients, recent experience suggests that the use of cryoprecipitate-poor plasma may not be more effective than the use of standard FFP as a specific replacement fluid for plasma exchange in patients with TTP. The effectiveness of plasma exchange in this setting may derive from removal of antibody to or replacement of the von Willebrand factor–cleaving zinc metalloprotease, ADAMTS13. However, patients with clinical features of TTP and only moderate ADAMTS13 deficiency or even normal activity may respond to plasma exchange. Plasma exchange for hematopoietic progenitor cell transplant recipients exhibiting clinical features of TTP, now generally referred to as transplantation-associated thrombotic microangiopathy (TAM), has proved far less efficacious. This syndrome likely differs in pathogenesis from classic TTP in many aspects, including the absence of severe ADAMTS13 deficiency, the spectrum of clinical symptoms, and the lack of evidence of systemic microthrombus formation. Furthermore, plasma exchange has been unsuccessful in reversing most cases of TAM.

Small, uncontrolled studies and extensive clinical experience support the use of plasmapheresis as an adjunctive therapy for patients with paraproteinemia and hyperviscosity syndrome and with some paraproteinemias in the absence of hyperviscosity. Comprehensive reviews describing the rationale and treatment schedules for plasmapheresis in patients with a variety of paraproteinemias, including cryoglobulinemia and Waldenström macroglobulinemia, and other hematologic-oncologic indications, have been published. Waldenström macroglobulinemia manifests as a lymphoplasmacytic lymphoma with a monoclonal IgM protein in the plasma. Because IgM is a large molecule and resides predominantly in the intravascular space, as little as one apheresis procedure will result in improvement in symptoms. Recurrence of symptoms and rising plasma viscosity will determine the need and frequency of repeated exchanges.

Low-Density Lipoprotein Apheresis and Other Metabolic Disease Indications

Evidence that cutaneous lesions and vascular lesions regress in individuals with familial hypercholesterolemia as LDL levels are controlled by plasmapheresis has encouraged the use of apheresis column absorption procedures in patients with homozygous disease and in poorly controlled heterozygous patients. LDL apheresis is a procedure for removing apolipoprotein B–containing lipoproteins from the blood by a variety of techniques, including dextran sulfate cellulose adsorption, immunoadsorption, and heparin-induced extracorporeal precipitation. Short-term safety and efficacy have been demonstrated. Patients have now been treated successfully for several years; however, additional experience with this therapy will be required to prove long-term benefit for refractory hypercholesterolemia and coronary artery disease for heterozygotes in particular.[18] In 36 homozygous children in two studies, 20% to 22% developed new aortocoronary lesions or showed progression of existing lesions while on apheresis despite impressive reductions in mean LDL cholesterol.[19,20] Side effects such as malaise, shivering, and pain at the phlebotomy site are common, but mild and the treatments are generally well tolerated. Patients with severe hypertriglyceridemia are at risk of developing acute pancreatitis. Plasma exchange appears to reduce the episodes of recurrent episodes by an average 67% but requires continuation of medical therapy.

Simple plasma exchange may be used in patients with other inherited metabolic diseases, such as Refsum disease. The frequency of exchange depends primarily on total body burden, rate of synthesis, and plasma concentration of the solute to be removed (Fig. 119-7). Less evidence exists to support a role for repeated treatments in these diseases.

Immune Disease Indications and Immunoadsorption Therapies

Plasma exchange appears to have at least a temporary adjunctive role in managing some rheumatic diseases and other immune disorders characterized by circulating autoantibodies. Early success was reported in patients with Goodpasture syndrome, a disorder characterized by a specific pathogenic autoantibody directed against the renal glomerular and pulmonary alveolar basement membrane. Plasmapheresis has demonstrated similar success in myasthenia gravis, pemphigus, and Eaton-Lambert syndrome. Although nonselective plasma exchange has been used in a variety of other rheumatic diseases such as systemic lupus erythematosus (SLE) and rheumatoid vasculitis, with the exception of treatment of patients with Goodpasture syndrome (in which plasma exchange is considered first-line adjuvant therapy), such use remains unproved and should be reserved for circumstances in which a vital organ or life itself is endangered. Selective leukapheresis by Adacolumn technology in a series of patients with SLE has shown clinical benefit, but trial interpretation is limited by the uncontrolled nature and small size.

In some immune disorders, such as immune thrombocytopenic purpura (ITP) and immune inhibitors to coagulation proteins, plasma exchange may be helpful during a catastrophic event, but in general, benefit of nonselective plasma exchange therapy is not established.

Plasma exchange appears to be a useful therapeutic option in renal transplant patients threatened with refractory humoral rejection and is now widely used to overcome ABO and HLA incompatibilities between renal transplant patients and their only available donors. Several studies have shown successful reversal of acute humoral rejection mediated by HLA-specific donor antibody using a combination of plasmapheresis and IV immune globulin (IVIG), which is superior to high dose IVIG alone.[21] A conditioning regimen consisting of pretransplant plasmapheresis, immunosuppressive medications, and low-dose cytomegalovirus immune globulin effectively reduces donor-specific antibody and isoagglutinin titers with and without posttransplant splenectomy and anti-CD20 treatment. The strength of donor-specific antibodies is also important and can be determined by titration, but greater sensitivity and specificity may be obtained using Luminex flow-bead technology. Patients with strong anti-HLA antibodies have increased mean bead fluorescence and were more likely to have acute rejection; however, the introduction of peritransplantation apheresis reduced this from 66% to 7%.[22]

Plasma exchange has also been used to treat patients with focal segmental glomerulosclerosis, both for primary disease refractory to standard immunosuppressive therapy and for treatment of patients with recurrent disease after renal transplantation.

Two immunoadsorption columns have been approved in the United States for removal of autoantibodies to factor VIII or factor IX (Immunosorba staphylococcal protein A–agarose column) and treatment of ITP and rheumatoid arthritis (Prosorba staphylococcal protein A–silica column). Several case series describe the use of immunoadsorption for patients with immune inhibitors to factor VIII or factor IX. A phase III, multicenter, sham-controlled randomized study of staphylococcal protein A column immunoadsorption shows a significant increase in clinical response in adult patients with longstanding rheumatoid arthritis. Sparse published evidence exists to support the use of immunoadsorption therapy in patients with chronic ITP refractory to standard medical management.

Plasmapheresis is effective first- or second-line therapy in selected patients with certain neurologic disorders. Controlled clinical trials of plasmapheresis have demonstrated efficacy in at least two of the polyradiculoneuropathies. In Guillain-Barré syndrome, plasmapheresis should be considered when patients are unable to walk independently or require mechanical ventilation. However, IVIG alone may be equally effective and is more readily available.[15] Periodic plasmapheresis may be necessary in patients with a chronic inflammatory demyelinating neuropathy. Because the long-term prognosis varies, plasmapheresis may be used in conjunction with steroids and IVIG. Rapid deterioration may occur upon discontinuation.

Multiple sclerosis (MS) is a relapsing and progressive disorder with demyelination of the central nervous system white matter. Patients who present with acute fulminant demyelination may benefit from early plasma exchange, particularly when they fail to respond to high-dose corticosteroids.[23] The majority of patients have a relapsing-remitting form of the disease, and plasmapheresis may be of benefit. Unfortunately, for chronic progressive forms of MS, plasma exchange has been constantly been shown to be ineffective.

REPLACEMENT FLUIDS FOR PLASMA EXCHANGE

The success of therapeutic apheresis procedures seldom depends on the composition of the replacement solution that is used; the single exception is TTP (discussed in the previous section). With therapeutic plasmapheresis for most other disorders, the primary function of the replacement solution is to maintain intravascular volume. Additional requirements include restoration of important plasma proteins, maintenance of colloid osmotic pressure, maintenance of electrolyte balance, and preservation of trace elements lost during a prolonged course of plasmapheresis procedures. In moderately well-nourished patients, homeostatic mechanisms normally obviate the need for precise plasma replacement, and 5% albumin in normal saline or combinations of albumin and crystalloid are usually sufficient. Commonly used is 60% to 80% replacement by colloid, with the crystalloid component consisting of a combination of normal saline and an anticoagulant. Patients with clinical conditions such as hypotension, hypoalbuminemia, or preexisting coagulopathies should receive solutions prepared specifically to meet their individual requirements. Routine supplementation with calcium, potassium, or immunoglobulins is unnecessary. However, for large-volume apheresis procedures to collect PBSCs, IV calcium supplementation is beneficial (discussed in the following section). Because less than 500 mL is removed during most cell collection procedures and therapeutic cell depletions, no volume replacement beyond the anticoagulant and saline priming solution is required. Problems of decreased availability and high cost of albumin have led some centers to develop protocols for alternatives to plasma derived volume expanders, such as hydroxyethyl starch (HES), for full- or partial-volume replacement with plasma exchange. One center has used a combination of 3% HES and 5% albumin mixture successfully, but patients did experience mild adverse events more frequently than historical control participants.[24] Although such solutions are generally well tolerated, extensive replacement with HES in patients undergoing longer courses of plasmapheresis, especially those with impaired renal function, can result in diffuse tissue accumulation of the larger starch molecules (acquired lysosomal storage).

COMPLICATIONS OF THERAPEUTIC APHERESIS

Automated apheresis is a minimal-risk procedure for normal healthy donors. The current generation of blood cell separators is remarkably reliable and equipped with sensitive detection and alarm systems to alert the operator to potential problems. Nevertheless, serious morbidity and rare deaths have been associated with therapeutic procedures. In most reports, deaths are related to either complications associated with the use of central venous access catheters or to cardiac and respiratory problems in patients who were critically ill before apheresis; in the latter, the contributory role of the apheresis procedure is often questionable. The most common adverse effects of therapeutic apheresis are citrate-induced hypocalcemia, allergic reactions (usually to donor plasma or other blood components), vasovagal reactions, and hypovolemia. If transient paresthesia and mild vasovagal events are excluded, approximately 5% of all therapeutic apheresis procedures have medical complications. The frequency of adverse reactions is influenced by the experience of the operator and the nature of the patient population being treated. Expected and predictable effects of therapeutic apheresis include alterations in laboratory parameters caused by removal and dilution by replacement fluids. A

5% to 15% decrease in hemoglobin and hematocrit, a 20% to 30% decrease in platelet count, and mild transient increase in leukocyte count are commonly observed. Significantly but transiently abnormal coagulation test results are often observed (recovery generally occurs within 48 hours after a single-volume exchange procedure), as well as clinically insignificant decreased levels of other plasma proteins after serial plasma exchange procedures. The most common adverse effect of both donor and therapeutic apheresis procedures is symptomatic hypocalcemia caused by infusion of calcium-chelating citrate ions in the anticoagulant, and if used as replacement fluid, anticoagulated donor plasma. Hypocalcemia is usually manifested by mild perioral or acral paresthesia, or both, requiring no intervention other than slowing the reinfusion rate. The benefit of oral calcium supplements in this setting is questionable, although the practice is widespread. Hyperventilation may exacerbate the symptoms of hypocalcemia. More severe citrate toxicity is uncommon; signs may range from involuntary carpopedal spasm, nausea, and vomiting to frank tetany with spasm in other muscle groups, including life-threatening laryngospasm and grand mal seizure. Severe toxicity is most commonly experienced by small patients, particularly women, when the blood flow rate is rapid and the procedure is prolonged beyond a few hours. Symptoms correlate inversely with the level of ionized calcium. Extremely low concentrations of ionized calcium are encountered routinely in therapeutic procedures that process more than 15 L of blood. Acute severe hypocalcemia leading to fatal cardiac arrhythmia has been reported in patients who have undergone apheresis. Controlled infusions of 10% calcium gluconate or calcium chloride are effective in the management of these complications. Because metabolism of citrate occurs predominantly in the liver and kidney, patients with conditions affecting these organs are at increased risk for severe citrate reactions. Studies of therapeutic plasma exchange procedures and of PBSC donations performed with and without calcium gluconate or calcium chloride infusion show the effectiveness of continuous calcium infusion for the prevention of mild to moderate citrate toxicity (Fig. 119-8). A study of plateletpheresis donors documented sustained effects of citrate infusion on bone metabolism demonstrated by changes in alkaline phosphatase, osteocalcin, parathyroid hormone, and 1,25-dihydroxyvitamin D levels, suggesting the potential for long-term effects on bone metabolism in these donors. Magnesium, another divalent cation, is also bound by citrate. Despite decreases in serum ionized magnesium levels to 39% below baseline, clinical effects are not typically observed even during large-volume leukapheresis procedures. The most severe allergic complications occur when plasma is used as the replacement solution, and this risk increases with repeated exposure. Allergic reactions to ethylene oxide, an agent used in the sterilization of plastic disposable equipment, have been reported. IV diphenhydramine is usually effective in managing allergic reactions; premedication with steroids and precautions against anaphylaxis may be necessary for sensitized individuals. Atypical (hypotension and flushing) and anaphylactic reactions have been reported in patients receiving angiotensin-converting enzyme inhibitors undergoing different apheresis procedures, including immunoadsorption with staphylococcal protein A columns. These medications should be discontinued for at least 24 hours before apheresis. Unlike donors undergoing apheresis for donation of RBCs, platelets, or plasma, donors undergoing apheresis for collection of therapeutic granulocytes are stimulated with steroids and granulocyte colony-stimulating factor (G-CSF) before donation. The well-known association of long-term steroid treatment and posterior subcapsular cataracts has not been believed to be relevant in the context of short-term steroid stimulation for donor granulocyte mobilization. However, an increased number posterior subcapsular cataracts was detected in two small studies and in 100 granulocyte donors compared with age-matched plateletpheresis donors, suggesting that granulocyte donors may be at increased risk for certain types of cataract formation. Repeated steroid stimulation for granulocyte collection warrants regular ophthalmologic examination and close follow-up.[25] Serious complications indirectly associated with therapeutic apheresis include adverse consequences of large-needle vascular access; namely, retroperitoneal or pericardial hemorrhage, pneumo- or hemothorax, thrombosis, nerve damage, and infection. A retrospective review of 381 therapeutic plasma exchange procedures at one institution reported an approximately 1% incidence of severe complications, all of them related to central venous catheters.

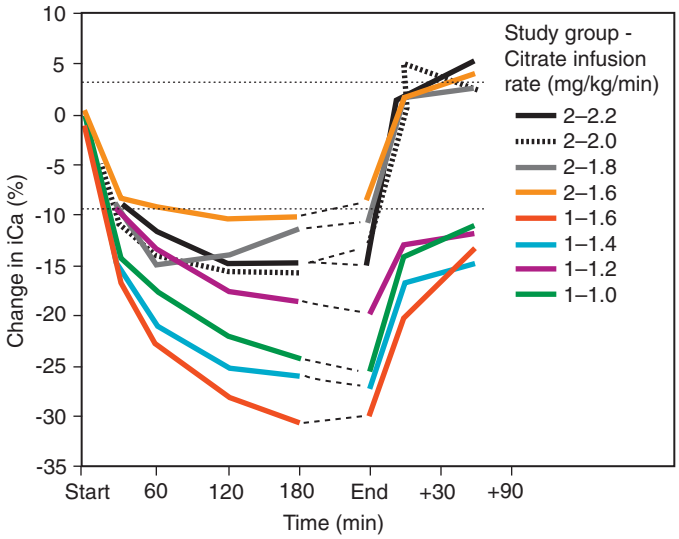

Figure 119-8 LEVELS OF IONIZED CALCIUM (iCa) ARE MARKEDLY LOWER IN PROCEDURES PERFORMED WITHOUT PROPHYLACTIC Ca INFUSION AND REMAIN BELOW THE REFERENCE RANGE 90 MINUTES AFTER COMPLETION OF APHERESIS. *Dotted lines* indicate upper and lower limits of the reference range. *Open symbols* represent procedures without prophylactic Ca; *solid symbols* represent those with Ca infusion. *Dashed lines* between 180 minutes and end-procedural values (End) reflect varying procedure duration. *(From Bolan CD, Cecco SA, Wesley RA, et al: Controlled study of citrate effects and response to i.v. calcium administration during allogeneic peripheral blood progenitor cell donation.* Transfusion *42:935, 2002, used by permission).*

HEMOPOEITIC STEM CELL COLLECTION

Blood cell separators developed for hemapheresis are used to collect peripheral blood cells for cellular therapy. The most common application of apheresis technology for cell therapy indications is the collection of HPCs from peripheral blood after administration of recombinant hematopoietic growth factor or chemotherapy, or both, to "mobilize" large numbers of HPCs into the circulation. The collected mononuclear cell fraction contains a subset of progenitor cells that, on infusion, can home to and reconstitute the bone marrow in patients who receive ablative radiation or chemotherapy or both. Similarly, donor leukocytes are obtained from leukapheresis procedures may be used for donor lymphocyte infusion or subject to further processing for immunotherapy.

Peripheral Blood Stem Cells

Pluripotent HPCs, and quite possibly primordial hematopoietic stem cells capable of reconstituting the bone marrow and the immune system, have long been known to circulate in the peripheral blood. Numerous studies have confirmed the potential for rapid and durable engraftment of PBSCs mobilized into the circulation by hematopoietic growth factors harvested by large-volume leukapheresis procedures and subsequently administered to patients with marrow aplasia after high-dose chemotherapy. The concentration of hematopoietic stem cells in the peripheral blood can be increased by the administration of cytokines such as G-CSF and granulocyte-macrophage colony-stimulating factor (GM-CSF) and by the administration of chemotherapy. $CD34^+$ hematopoietic cell numbers in the peripheral

blood generally rise 20- to 40-fold (from 1 to 3 cells/μL to 40 to 70 cells/μL) after administration of G-CSF alone, and they increase 100- to 1000-fold when chemotherapy rebound is enhanced by administration of G-CSF. Efforts to define optimal collection conditions have been limited by the lack of a standardized assay; however, time and level of increase of donor peripheral blood WBC and $CD34^+$ cell counts after administration of mobilizing agents have proved to be useful indicators. Despite ongoing problems with interlaboratory standardization, flow cytometric analysis of cells labeled with a fluorochrome-conjugated CD34 antibody are used for "real-time" decision making about the timing and adequacy of PBSC collections. Several prestimulation donor variables are important. Increasing age, white ethnicity, and female gender are associated with significantly lower post–G-CSF $CD34^+$ cell counts, which would favor younger males as donors when high cell doses are required.[26]

Several clinical scale devices for $CD34^+$ cell enrichment of leukapheresis collections by immunoabsorption or immunomagnetic techniques are available. This "positive selection" of $CD34^+$ hematopoietic cells also results in reduced numbers of cells that do not express the CD34 antigen, such as T lymphocytes. T cell–reduced products may confer a lower risk of GVHD, and the ability to produce apheresis products enriched for $CD34^+$ cells facilitates graft manipulations for experimental cell therapies such as ex vivo expansion of $CD34^+$ cells. However, some studies suggest a higher incidence of engraftment failure and possibly delayed immune reconstitution in certain patient populations when transplants are performed with highly purified CD34-selected, T cell–depleted products.

Several problems have slowed enthusiastic universal adoption of PBSC transplants for all recipients. Concerns remain regarding the hypothetical long-term effects of exposure of healthy donors to growth factors. The possible risks of donor G-CSF administration and leukapheresis must be weighed against less evidence of benefit of PBSCs compared with bone marrow (or against the rapid availability of cord blood) for pediatric recipients. Also, some clinical data suggest the possibility that allogeneic PBSC transplant may result in more frequent chronic GVHD in certain patient populations than occurs with bone marrow transplant without obvious reciprocal benefit with regard to graft-versus-leukemia effect. For allogeneic donors, the discomfort and inconvenience of multiple-day cytokine administration may be a significant deterrent. Most donors experience some degree of malaise and bone pain, and some donors require hospitalization for more serious adverse reactions to G-CSF administration. A large prospective trial of the National Marrow Donor Program found female donors at greater risk of apheresis adverse events and more frequently required central line insertion.[27] Splenic enlargement occurs commonly, and several instances of splenic rupture have been reported. Citrate toxicity is a common complication of PBSC collections; although usually mild and transient, it may be severe and even life threatening in some individuals (see previous section). Venous access requires large-bore multilumen catheters, and these appear particularly susceptible to clotting, especially when patients receive recombinant cytokine stimulation. Hemorrhage, especially in thrombocytopenic patients, is another potentially severe complication of central venous catheter placement.

Some patients who have received multiple prior cycles of chemotherapy and a small proportion of normal healthy donors, referred to as "poor mobilizers," fail to respond adequately to mobilization regimens. In this circumstance, Plerixafor, a reversible CXCR4 antagonist that can block the adhesion of HPCs to the bone marrow stroma can enhance collections by releasing these cells into the circulation. In a randomized controlled trial, the combination of G-CSF and Plerixafor resulted in a significantly higher proportion of patients with non-Hodgkin lymphoma achieving their target cell dose in fewer apheresis days.[28] Similar success is achieved with multiple myeloma patients achieving a 4.8-fold increase peripheral blood CD34 cell count compared with 1.7-fold with G-CSF alone.[29] Emerging evidence indicates that Plerixafor may be administered to rescue collections for patients who mobilize poorly with G-CSF alone; however, the optimum timing for administration has not yet been determined.[30]

Patient Management Issues for Therapeutic Apheresis

Important issues to consider when preparing a patient for therapeutic apheresis, for monitoring the patient during the procedure, and for managing the patient after removal from the apheresis device include:

Preparation

- Volume considerations—Calculate volume to be processed or exchanged; order replacement solutions; assess patient volume status. A blood prime may be necessary for children who weigh less than 25 kg.
- Vascular access—Assess need for apheresis line placement. Note that not all large catheters are suitable for apheresis procedures.
- Medications—Evaluate impact of medications (Coumadin, platelet inhibitory agents, angiotensin-converting enzyme inhibitors) and indications to suspend certain medications. Albumin-bound medications may be depleted by apheresis.
- Cell counts—Patient may require transfusion for preprocedure anemia or thrombocytopenia.
- Electrolytes—Assess risks for citrate toxicity; order calcium replacement solutions if indicated.

Procedure

- Volume considerations—Monitor replacement fluids (saline-to-albumin ratio). Rapid infusion of refrigerated solutions may cause hypothermia.
- Vascular access—Observe for impaired, intermittent, or obstructed flow. Kinked tubing can result in hemolysis.
- Medications—Limitations on blood or citrate flow rate caused by symptomatic citrate-induced hypocalcemia may necessitate addition of anticoagulant to the final apheresis product or inclusion of heparin in the anticoagulant regimen.
- Cell counts—Consider the impact of very high or low cell counts on device settings and procedure efficiency.
- Electrolytes—Continually monitor for adverse citrate effects; bolus or continuous intravenous calcium administration may be required.

Postprocedure Management

- Volume considerations—Review net volume balance and consider additional infusion or administration of diuretic if needed.
- Vascular access—The decision to remove the apheresis catheter should include the possibility of additional apheresis or procedures; monitor for complications associated with maintenance or removal of venous catheter.
- Medications—Determine when to restart medications; consider the impact of transiently reduced coagulation factor levels.
- Cell counts—The patient may require transfusion for postprocedure thrombocytopenia; monitor cumulative red blood cell and platelet loss after repeated procedures.
- Electrolytes—Assess for imbalance postprocedure with attention to ionized calcium and magnesium as indicated by symptoms.

PEDIATRIC HEMAPHERSIS

Therapeutic apheresis in pediatrics poses a particular challenge. The indications for apheresis in children are limited by a lack of clinical trial data in this population. Therefore, the evidence for therapy in many diseases is extrapolated from trials in adults despite differing patient physiology and an age-dependent presentation and natural history of the disease. For example, hemolytic uremic syndrome is

more common in children and responds to supportive care; at the other spectrum of this disease, TTP is more common in adults and necessitates plasma exchange.

Similarly, the mechanics of apheresis was developed for adults and therefore designed for their larger circulating blood volume. Therefore, depending on the size of the child, modifications to the apheresis procedure may be necessary. Central venous catheters are required in most circumstances because the caliber of peripheral venous access is too small in most circumstances to permit adequate blood flow.

Technical Aspects

In pediatric apheresis, maintenance of isovolemia is essential to prevent circulatory compromise, particularly in an acutely ill patient who may have some degree of cardiac or renal impairment. The beginning and end of the apheresis procedure involves negative and positive intravascular fluid shifts, respectively. Typically, this has negligible impact on an adult's circulation but can represent a substantial proportion of the total blood volume (TBV) of an infant. The volume of the patient's blood required to fill the apheresis tubing and circuit at the start of the procedure is the extracorporeal volume (ECV). Symptomatic hypovolemia is possible when this exceeds 15% of TBV. For example, when the ECV is 400 mL, this represents 8% of the TBV in a 70-kg patient but may be as much as 35% for a 15-kg infant. Therefore, modification of the apheresis procedure is necessary if this is to be performed safely in infants and children.

In adults, the apheresis circuit is primed with saline, which is then diverted to the collection or waste bag. One option permits return of saline prime to the patient, which may be useful for larger children. For children who weigh less than 25 kg, a prime with RBCs is often necessary to prevent intravascular volume depletion. RBCs are chosen over pure crystalloid solutions alone to prevent a RBC deficit. This is important for patients sensitive to a drop in intravascular RBC volume. Upon completion, fluids remaining in the apheresis circuit, typically returned to the adult patient, are not returned in pediatrics to avoid a positive fluid shift causing fluid overload.

Pediatric Apheresis

The majority of apheresis procedures in children are erythrocytapheresis for patients with sickle cell disease and mononuclear cell collections for HPCs to be used in conjunction with high-dose chemotherapy. Plasma exchange is infrequently indicated apart from uncommon neurologic disorders. For example, pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (PANDAS) and Sydenham chorea (SC) are autoimmune neuropsychiatric disorders that occur rarely after infection with group A β-hemolytic streptococcal infections. Circulating immune factors may be part of the pathogenesis of these diseases because both respond to IVIG and plasmapheresis. In a small randomized study, 50% of patients with SC also responded to plasmapheresis, and although superior to corticosteroids, treatment with IVIG had the best response, with 72% of patients having a reduction in symptoms of chorea.

CHAPTER 120

TRANSFUSION REACTIONS TO BLOOD AND CELL THERAPY PRODUCTS

Jacquelyn D. Choate, Robert W. Maitta, Christopher A. Tormey, YanYun Wu, and Edward L. Snyder

A *transfusion reaction* can be defined as any untoward reaction that occurs as a consequence of infusion of blood or cell therapy products. Transfusion reactions can be classified as acute or delayed. Acute reactions occur during the transfusion or within several hours after its completion. Delayed transfusion reactions occur at any point after this time frame; for example, delayed hemolytic transfusion reactions typically present days after the transfusion. Other types of delayed reactions may present long after the actual transfusion—months or even years later, as in the case of some transfusion-transmitted diseases. From 2005 to 2010, there were 307 transfusion related fatalities reported to the FDA.[1] This chapter will review various types of transfusion reactions (Table 120-1).

HEMOLYTIC TRANSFUSION REACTIONS

Hemolytic transfusion reactions are caused by the immune-mediated lysis of transfused red blood cells (RBCs). Immune-mediated hemolysis can be classified according to the timing of the reaction (acute or delayed) and by site of hemolysis (intravascular or extravascular). The four types of hemolytic transfusion reactions are acute intravascular, acute extravascular, delayed intravascular, and delayed extravascular (Table 120-2).[1,2]

ACUTE INTRAVASCULAR HEMOLYTIC TRANSFUSION REACTIONS

Acute reactions are those that occur within minutes after incompatible RBCs are transfused into a patient who already possesses the corresponding antibody. Because ABO antibodies are naturally occurring (and primarily IgM class or a mixture of IgG and IgM class), infusion of ABO-incompatible blood is the most likely cause of a clinically significant acute intravascular hemolytic transfusion reaction. However, other complement-fixing antigen-antibody systems, such as alloantibodies with specificity for the Jk^a (Kidd) blood group system, can also produce these reactions in situations where they are undetectable in the pretransfusion sample. Such a reaction could occur, for example, after transfusion of A RBCs into an O recipient who has significant amounts of circulating anti-A. Although the titer and avidity of the antibody affect the extent of the hemolytic reaction, the clinical severity of an incompatible RBC transfusion is greatly influenced by the degree of complement activation and cytokine stimulation. The transfused incompatible RBCs undergo complement-mediated osmotic lysis, producing hemoglobinemia and hemoglobinuria. The sine qua non of an acute intravascular hemolytic transfusion reaction is the presence of red plasma and red (dark) urine.

It is critical to distinguish, as quickly as possible, hemoglobinuria and hemoglobinemia resulting from an acute hemolytic transfusion reaction from similar signs due to other causes. Hemoglobin in the urine can be confused with myoglobin or with hematuria from a urinary tract source. Hemoglobinemia caused by non-immune-mediated lysis can result from mechanical hemolysis from an improperly collected blood sample. The direct antiglobulin test (DAT) usually becomes positive in an immune hemolytic reaction (if tested before all the incompatible RBCs are destroyed); preparation of an antibody eluate is often necessary to identify the presence of an offending IgG antibody. An elution is a procedure that chemically separates the bound antibody from the RBCs and concentrates it so that it may be identified.

If time is lost in making a clinical diagnosis, a mild treatable reaction can quickly turn into one that is life threatening. An acute intravascular hemolytic transfusion reaction is a true medical emergency. Initial clinical symptoms can include fever and chills, shortness of breath, chest pain, dizziness, and back or flank pain. Some patients report feeling pain or warmth ascending from the site of infusion, or a feeling of anxiety or "impending doom." Acute transfusion reactions can quickly progress to shock and acute renal failure. In an ABO-incompatible transfusion reaction, activation of the complement cascade occurs with release of C3a and C5a (anaphylatoxins 1 and 2, respectively). Fixation of the C5b-9 complement membrane attack complex produces pores in the RBC membrane, resulting in osmotic lysis. Antibody-coated RBC stroma produced during an immune hemolytic transfusion reaction induces renal vasoconstriction, resulting in acute tubular necrosis. Another contributing cause of ischemic renal failure involves the release of free plasma hemoglobin. It has been shown that cell-free hemoglobin binds tightly to nitric oxide. Endothelium-derived relaxing factor, a powerful vasodilator, is composed in part of nitric oxide. By binding to nitric oxide, free plasma hemoglobin blocks relaxing factor and prevents renal vasodilation. This also promotes renal vasoconstriction and renal tubular ischemia, with eventual tubular necrosis. Many patients, curiously even anephric patients, often complain of lower back pain. It is speculated that this symptom is caused by ischemic muscle pain or vasospasm, rather than by kidney pain from developing renal failure. In addition to complement components, cytokines and interleukins (ILs) also play a role in the clinical symptom complex, including fever, associated with acute intravascular hemolytic transfusion reactions. For example, IL-1β, IL-6, and tumor necrosis factor-α (TNF- α) have pyrogenic activity; IL-8 is a neutrophil chemotactic and activating factor. These four cytokines have been generated in various in vitro models of intravascular hemolysis and IgG-mediated RBC incompatibility. The clinical variability of hemolytic transfusion reactions is likely explained by the relative balance of cytokine production in the transfusion recipient. Factors that increase the circulating levels of proinflammatory cytokines and chemokines often result in more severe reactions.

Laboratory Evaluation

Laboratory findings include hemoglobinuria, hemoglobinemia, and a haptoglobin level that is low to undetectable. During the hemolytic episode, the bilirubin (especially indirect bilirubin) usually increases only to 2 to 3 mg/dL if the patient has normal liver function. Elevations of bilirubin to 20 to 30 mg/dL are not seen in otherwise normal patients, even with florid hemolysis. Very elevated bilirubin levels are seen only in patients with concurrent hepatocellular disease, such as viral hepatitis or hepatic carcinoma. Because of the lysis of RBCs, levels of lactate dehydrogenase (LDH) may rise markedly. If the patient shows no signs of vasomotor instability and if hemostatic and

Table 120-1 Types of Acute Transfusion Reactions

Reaction Type	Presenting Signs and Symptoms
Acute intravascular hemolytic	Fever, chills, dyspnea, hypotension, tachycardia, flushing, vomiting, back pain, hemoglobinuria, hemoglobinemia, shock
Acute extravascular hemolytic	Fever, indirect hyperbilirubinemia, posttransfusion hematocrit increment lower than expected
Febrile reaction	Fever, chills
Allergic (mild)	Urticaria, pruritus, rash
Anaphylactic	Dyspnea, bronchospasm, hypotension, tachycardia, shock
Hypervolemic	Dyspnea, tachycardia, hypertension, headache, jugular venous distention
Septic	Fever, chills, hypotension, tachycardia, vomiting, shock
Transfusion-related acute lung injury	Dyspnea, decreased oxygen saturation, fever, hypotension

Table 120-2 Hemolytic Transfusion Reactions: Serologic Presentation

Type	Antibody Detectable Initially	Primary Antibody Type	Degree of Complement Binding	Example
Acute intravascular	Yes	IgM	Full (C1-9)	ABO system
Acute extravascular	Yes	IgG	None/partial	Rh system
Delayed intravascular	No	IgG	Full (C1-9)	Kidd system
Delayed extravascular	No	IgG	None/partial	Duffy system

renal function is unchanged 24 to 36 hours after the incompatible transfusion, the episode can be considered to be over, with serious sequelae unlikely.

Therapy

Initial therapy consists of immediately stopping the transfusion, maintaining a patent intravenous line, cardiorespiratory support, and ensuring a brisk diuresis. Increasing renal blood flow is the best way to prevent acute oliguric renal failure. Usually, 0.9% NaCl or some other suitable crystalloid solution is infused to maintain a urine output of 100 mL/hour for approximately 24 hours. Diuretics, such as furosemide, also can be used and are preferred by some to infusion of mannitol to increase intravascular volume. Mannitol, if chosen, must be used with caution; if acute tubular necrosis (ATN) occurs before mannitol infusion, pulmonary edema may occur as a result of the acute increase in intravascular volume secondary to fluid expansion. Similarly, excessive crystalloid infusion should be avoided in patients with fluid overload, including those patients with congestive heart failure. Renal damage must be minimized, however, and increasing renal blood flow helps to prevent anuric renal failure. The mechanisms responsible for the beneficial effect of increased renal blood flow likely include increased clearance of free hemoglobin, resulting in decreased binding of nitric oxide, and a return of more physiologic control of renal vasodilation. Creatinine and blood urea nitrogen (BUN) should be closely monitored; dialysis may be necessary for treatment of oliguric acute renal failure. Support of blood pressure and respiration may require the use of vasopressors, bronchodilators, and when necessary, intubation. High doses of dopamine cause vasoconstriction and should be avoided unless required to support the patient's blood pressure. Disseminated intravascular coagulation (DIC) can occur in severe cases. The prothrombin time, partial thromboplastin time, and fibrinogen level should be closely monitored (see box on Workup of an Acute Intravascular Hemolytic Transfusion Reaction).

Workup of an Acute Intravascular Hemolytic Transfusion Reaction

If an acute transfusion reaction occurs:

1. Stop blood component infusion immediately.
2. Maintain intravenous access with a suitable crystalloid or colloid solution.
3. Monitor/maintain blood pressure and heart rate.
4. Maintain an adequate airway.
5. Give a diuretic or institute fluid diuresis, or both.
6. Obtain blood and urine studies for the transfusion reaction workup.
7. Blood bank workup of suspected transfusion reaction:
 - Check paperwork to ensure correct blood component was transfused to the correct patient.
 - Observe plasma for hemoglobinemia.
 - Perform direct antiglobulin test.
 - Repeat compatibility testing (crossmatch).
 - Repeat other serologic testing as needed (ABO, Rh).
 - Analyze urine for hemoglobinuria.

If intravascular hemolytic reaction is confirmed:

8. Monitor renal status (BUN, creatinine).
9. Monitor coagulation status (prothrombin time, partial thromboplastin time, fibrinogen).
10. Monitor for signs of hemolysis (lactate dehydrogenase, bilirubin-total/direct, haptoglobin).
11. If sepsis is suspected, culture as appropriate.

ACUTE EXTRAVASCULAR HEMOLYTIC TRANSFUSION REACTION

In an extravascular hemolytic transfusion reaction, complement is either not fixed at all or is fixed only to C3b. In either situation, because of the nature of the antigen-antibody reaction, complement activation with fixation of the C5b-9 complex does not occur. This presentation is commonly associated with Rh antibodies, but can be seen with any number of non-ABO antigen-antibody complexes. The presence of IgG bound to the RBCs or C3b fixation results in an extravascular reaction because the antibody-coated cells are cleared by the IgG receptors in the spleen or the C3b receptors in the liver. In these circumstances, RBC lysis does not occur in the intravascular space. Because of the lack of generation of C3a or C5a, an extravascular hemolytic transfusion reaction does not usually present as a clinical emergency. It is characterized by development of a positive DAT due to recipient RBC alloantibodies binding to the incompatible circulating donor RBCs. Moreover, an increase in indirect bilirubin, an increase in LDH, a decrease in hematocrit, a decrease in haptoglobin, and an increase in colorless urine urobilinogen can occur, but hemoglobinuria and hemoglobinemia are rarely present. The patient typically remains clinically stable; renal failure, shock, and hemostatic abnormalities, such as DIC, are rarely seen unless the amount of incompatible blood infused is excessive. However, patients often have a low-grade fever, probably from the generation of IL-1 or other proinflammatory cytokines.

When an extravascular hemolytic transfusion reaction is suspected, the diagnostic test of choice is a DAT with an eluate. The

eluate is performed to identify the antibody coating the RBCs. The positive DAT result reflects the patient's antibody (or antibodies) coating the incompatible donor RBCs. Because this is not an autoantibody (or antibodies), the patient's own RBCs are not usually involved in the reaction.

Typically, an acute extravascular hemolytic transfusion reaction requires no special therapeutic intervention. Maintaining a good urine output and monitoring renal and hemostatic function are usually sufficient. The patient characteristically recovers in a few days as the offending donor RBCs are cleared from the circulation. The pathogenic alloantibody can often be identified in the patient's serum/plasma. These extravascular acute reactions may occur if the patient's pre-existing alloantibody was missed by the blood bank during the antibody screening process, if a wrongly labeled sample was used, if the unit of blood was labeled for the wrong patient, or if the unit was hung, in error, on the wrong patient.

DELAYED HEMOLYTIC REACTIONS

The pathogenesis of a delayed intravascular transfusion reaction is similar to that described for an acute intravascular hemolytic reaction.[2,3] However, in the delayed type, the patient develops the antigen-antibody reaction some time (usually at least 3-10 days) after the transfusion. The process occurs more slowly and is less likely to present as a clinical emergency. Hemoglobinuria and hemoglobinemia can occur but often are less pronounced than with an acute intravascular reaction. This probably is due to the continual and gradual removal of antibody-coated RBCs as the antibody titer rises and by the more gradual generation of C3a and C5a. The same serologic diagnostic and treatment concepts used for an acute intravascular hemolytic reaction apply here. However, the need for acute intervention is much less likely. Initiating a diuresis and monitoring renal and hemostatic function may be sufficient.

Delayed extravascular hemolytic transfusion reactions occur as well and are, in fact, the most common presentation resulting from an anamnestic antibody response. Such antigen-antibody reactions often involve the Rh system. The clinical presentation is similar to that of an acute extravascular reaction: the patient often has no acute sequelae such as shock or DIC, but may present with a fever, a falling hematocrit, and the development of a new DAT with a positive eluate. Because these reactions are typically mild in nature, they are usually addressed with supportive care only.

One final note regarding the serologic evaluation of a transfusion reaction: posttransfusion testing may be complicated and difficult to interpret because of the possibility of autoantibodies or the involvement of medications. In such circumstances, referral to the pretransfusion specimen is often helpful (because the DAT or other testing may show positive results in these specimens). In cases of more complex evaluations, consultation with an expert serologist is recommended to better detect and identify new alloantibodies in the patient's serum, which may be responsible for a hemolytic transfusion reaction.

FEBRILE NONHEMOLYTIC TRANSFUSION REACTIONS

A febrile nonhemolytic transfusion reaction (FNHTR) is suspected when a transient temperature rise of 1° C or more occurs during or after transfusion and when no other cause for the fever can be identified.[3] In addition to fever, FNHTRs are often associated with shaking chills. In fact, shaking chills can also manifest without a concomitant fever, an atypical or "afebrile" FNHTR. In these cases, temperature increases may be masked by antipyretic premedication. Febrile reactions are likely mediated in part by cytokines released in response to antibody-leukocyte or antibody-platelet interactions. Cytotoxic or agglutinating antibodies having human leukocyte antigen (HLA) specificity, neutrophil specificity, or platelet specificity may be present in the recipient's plasma and react against antigens present on transfused donor lymphocytes, granulocytes, or platelets.[4] Conversely, donor plasma may contain the offending antibody that can react with the corresponding cellular antigens in the recipient's blood. The febrile reaction is mediated largely by the release of cytokines such as IL-1β, IL-6, and TNF-α from macrophages, monocytes, granulocytes, or lymphocytes. IL-1 (endogenous pyrogen), through prostaglandin PGE_2 synthesis, probably stimulates the thermoregulatory center of the hypothalamus to produce fever. Other mediators such as macrophage inflammatory proteins (e.g., MIP-1) may also participate in the febrile response, but this reaction is not mediated through prostaglandin synthesis. CD154 (CD40 ligand) derived from platelets may also be involved in febrile reactions by inducing cyclooxygenase-2 and PGE_2.[5]

Studies have shown that generation of cytokines does occur in units of blood during storage and that such generation is directly proportional to the leukocyte count of the unit and the duration of storage. Use of third-generation prestorage leukocyte reduction filters can lower the incidence of febrile reactions.[6] However, proinflammatory cytokines are not removed by bedside blood filters, and they enter the circulation. Prevention of cytokine generation by prestorage leukoreduction is more efficient and effective than is scavenging of the biologic response modifiers by using bedside filtration technology.

The frequency of febrile reactions for a non-leukoreduced unit has been estimated to be 6.8 per 100 units RBCs transfused and 2.2 per 100 units platelet transfused.[3] With the advent of prestorage leukoreduction these risks have been decreased to about 0.09 to 1.1 per 100 units RBCs transfused and 0.04 to 1.56 per 100 units platelet transfused. Reactions are most commonly seen in recipients who have been exposed to multiple white cell or platelet antigens. Oncology patients are at risk as a result of frequent transfusions, as are multiparous women who may have received multiple exposures during pregnancy and childbirth. Both of these groups of patients can form multiple HLA-, granulocyte-, or platelet-specific antibodies that will react with white cells or platelets upon subsequent exposure. Antigen-antibody reactions are capable of stimulating cellular activation with resultant complement fixation, cytokine generation, and activation of other biologic response modifiers.

Laboratory Evaluation

The workup of a febrile reaction must be undertaken promptly, because fever may also be the first sign of other, more severe reactions, including acute hemolysis or sepsis. A hemolytic transfusion reaction may be ruled out by reconfirming the ABO and Rh type of the patient and the donor unit, repeating crossmatching to confirm patient-donor compatibility, evaluating the results of the pretransfusion and posttransfusion direct antiglobulin tests, evaluating the serum for hemolysis, and rechecking the accuracy of paperwork. The posttransfusion DAT should yield negative findings, because FNHTRs do not involve RBC alloantibodies.

As laboratory testing is being completed, the workup should extend beyond the blood bank to include bedside patient evaluation. Fever and chills also may be caused by drugs or underlying diseases, or they may be associated with infection or inflammation. Neutropenic fever often complicates the clinical picture in patients undergoing high-dose chemotherapy, a population of patients likely to undergo repeated RBC or platelet transfusions. To rule out a septic transfusion reaction, blood cultures of the patient and the blood product should be considered, especially if the patient has very high fever or shows signs of sepsis (see later text for a more in-depth discussion of septic transfusion reactions). The difficulty lies in knowing when to order blood cultures, because they are expensive and there is a 3% incidence of false-positive cultures as a result of contamination during culturing. Most routine hospital blood banks do not have the expertise or reagents needed to identify specific HLA, platelet, or granulocyte antibodies. Accordingly, the diagnosis of an FNHTR is usually made as a diagnosis of exclusion without isolating an identifiable antibody.

Treatment and Prevention

Fever from an FNHTR usually responds to antipyretics, including aspirin, nonsteroidal antiinflammatory drugs (NSAIDs), and acetaminophen. For thrombocytopenic adult patients, acetaminophen is the antipyretic of choice. Aspirin and NSAIDs should be avoided in thrombocytopenic patients, because they further compromise platelet function because of their inhibitory effects on platelet cyclooxygenase. Diphenhydramine is not indicated for treatment of febrile reactions.

For patients with no history of febrile reactions, routine premedication is unnecessary. Those with a history of febrile reaction may be premedicated with acetaminophen or an NSAID. Those patients with severe reactions despite premedication may require more intensive pharmacotherapy, including hydrocortisone 1 to 2 hours before transfusion. Patients with severe shaking chills can be treated with meperidine, which can stop shaking chills almost immediately. Febrile reactions after granulocyte transfusions and, less frequently, after platelet transfusions can be so severe that hypotension and cardiovascular collapse may occur.

Prevention of febrile reactions when pharmacologic therapy fails relies on the use of leukocyte-depleted blood components. Several leukocyte depletion techniques are available. Centrifugation can remove approximately 70% of the leukocytes in a unit of blood; cell washing or use of frozen deglycerolized RBCs can remove up to 95% of contaminating white cells. Older microaggregate blood filters can reduce leukocyte content by approximately 1 to 2 logs (90%-93%). Third-generation leukocyte-depletion RBC filters are more useful for preventing febrile reactions.[7] They can remove up to 4 logs (99.99%) of white cells, often lowering the level of white cells in a unit of blood from 10^9 to 10^5. They also may be useful for preventing or delaying the onset of HLA alloimmunization. Leukocyte depletion platelet filters are also available. Recommendations for usage of leukocyte-depleted blood components are published. Data show that a patient who has had one febrile transfusion reaction has a 1 in 8 chance of having another one. Individuals with a history of recurrent severe febrile reactions should have notations made in their blood bank record to ensure future use of leukocyte-reduced components. Although clearly indicated for patients with multiple and recurrent febrile reactions, some physicians still question whether leukodepleted blood products should be used for all patients.

ALLERGIC AND ANAPHYLACTIC TRANSFUSION REACTIONS

Allergic Reactions

Allergic transfusion reactions are believed to be most commonly caused by infusion of plasma proteins (e.g., haptoglobin) against which recipients have formed IgE or IgG class antibodies.[3,8] The allergic manifestations produced vary. They can include erythema with associated mild to extensive urticaria and mild to intense pruritus; severe vasomotor instability; bronchospasm; and anaphylaxis. A patient who develops hives and a mild allergic reaction during a blood transfusion usually does not progress to a more severe anaphylactic reaction after infusion of additional blood from the same unit. The severity of allergic transfusion reactions is not necessarily dose related.

The exact nature of the antibodies involved in the various types of allergic reactions is unclear. The mild allergic reactions are usually IgE mediated, but other classes of immunoglobulins may also be involved; anaphylactic reactions are most often IgE mediated.[3,7] Allergic reactions are believed to be mediated by histamine. Histamine can be released through the antigen-antibody interactions involving antibodies present in recipients against donor antigens or via antibodies passively transferred from donor against recipient antigens. Histamine can also be passively transferred from donors to recipients by transfusion of stored blood components. Allergic transfusion reactions are quite common, occurring in approximately 1% of all transfusions. Most of these reactions start with pruritus, followed by the development of hives. At this point, the transfusion should be stopped and the patient given 25 to 50 mg of diphenhydramine, if there are no medical contraindications and if the patient had not already been maximally premedicated. After a short interval, the transfusion can resume, but only if the rash decreases or the hives disappear and the patient feels well without signs of fever, chills, or vasomotor instability; re-initiation of transfusion is possible in most cases because such allergic symptoms are not likely to recur. The risk for transfusion-transmitted disease posed by infusion of another unit of blood is greater than the risk posed by continuing a transfusion that has produced only mild urticaria.

Allergic transfusion reactions do not generally recur, but patients who have had more than one mild allergic reaction should continue to receive routine units and may be premedicated with diphenhydramine or other H_1 blockers (e.g., ranitidine). Washed RBCs or plasma-reduced platelets can be used to prevent severe recurrent reactions. Leukocyte depletion or microaggregate filters are of no value because the plasma protein passes through the filter. Corticosteroids, provided in advance of a transfusion, also may be useful in patients with serious recurrent reactions unless contraindicated.

Although it is convenient to characterize a transfusion reaction as being purely febrile or allergic, in reality there is often a mix of the two symptoms, and the reaction is designated according to the predominant clinical sign.

Anaphylactic Reactions

Although any number of proteins can mediate severe allergic reactions, it has been observed that plasma containing IgA, when transfused to patients with IgG or IgE class anti-IgA antibodies, is the most common cause of anaphylactic transfusion reactions. It is not routine to test a patient's plasma for IgG or IgE class anti-IgA, and such assays are not readily available. This type of reaction may also occur in patients with deficiency of other plasma proteins such as haptoglobin. Anaphylactic reactions are often associated with severe hypotension, respiratory distress, and even cardiovascular collapse. As such, these reactions can be life threatening and may require intubation, pressor agents, and use of potent antiallergic medications (e.g., epinephrine) to overcome the severe symptoms. If a clear cause for an anaphylactic reaction is found (e.g., an anti-IgA antibody in an IgA deficient recipient), then the use of product washing is appropriate. In addition, for patients with evidence of severe or recurrent allergic/anaphylactic reactions, a combination of H_1 and H_2 blockers may be more effective for treatment and premedication, and again, the addition of corticosteroids may be necessary if not otherwise contraindicated.

HYPOTENSIVE TRANSFUSION REACTION

A less recognized, but occasionally severe acute transfusion reaction is isolated hypotension during or immediately following a blood product infusion.[3] The classic presentation of such acute hypotensive reactions includes (a) a drop in blood pressure (often >30 mm Hg) as the main symptom and (b) hypotension occurring within minutes of the start of the transfusion and resolving quickly after the stop of the transfusion. This type of transfusion reaction was initially reported after transfusion of platelets administered through some types of bedside leukoreduction filters. Later, it was also reported in other types of blood products including plasma and RBCs. The pathogenesis of this syndrome appears to be related to the activation of the contact pathway (prekallikrein converting to kallikrein) induced in plasma by the negatively charged surface of some leukoreduction filters. Kallikrein activation stimulates the conversion of high-molecular-weight kininogen to bradykinin. Notably, these reactions have also been reported in cases where leukoreduction filters were used before storage, indicating that bradykinin generation may occur

via pathways other than via bedside filtration alone. The syndrome is often much more severe in patients already taking angiotensin-converting enzyme (ACE) inhibitors. ACE is identical to kininase II, which is responsible for degrading bradykinin. Blockage of the kininase II degradation of bradykinin by ACE inhibitors results in a prolonged bradykinin half-life and a reaction that can be very severe.

Hypotensive transfusion reactions are typically self-limited, as discussed above, since the hypotension often resolves upon cessation of transfusion. For patients with prolonged hypotension, the use of fluids to increase blood pressure may be warranted. Finally, although rare, pressors may also be indicated for patients with blood pressures unresponsive to simple fluid infusion alone.

INFECTIOUS COMPLICATIONS OF TRANSFUSION

Septic Transfusion Reactions

Bacterial contamination of stored blood can pose grave risks to the recipient. Bacteria can enter the blood bag during venipuncture (as a result of inadequate skin preparation), during component preparation, or through the collection of blood from a donor with an occult infection or asymptomatic bacteremia.[3] Bacteria that grow optimally at refrigerated blood bank temperatures (1° C to 6° C), including *Pseudomonas, Yersinia, Enterobacter,* and *Flavobacterium,* are organisms commonly associated with a contaminated unit of RBCs. Platelet concentrates, stored at room temperature, are also known to be subject to bacterial contamination; several reports have described fatal septic transfusion reactions due to platelets containing *Salmonella* or *Staphylococcus*. Units of blood that are contaminated need not be obviously discolored, malodorous, or clotted; by simple visual inspection, it is extremely difficult to determine whether a unit is contaminated. However, Kim and coworkers[9] reported that visual inspection, including comparison of the blood bag segmented tubing with that of the blood bag itself, can occasionally identify units of RBCs likely to be bacterially contaminated.

Patients who receive a unit of contaminated blood may develop high fever, rigors, skin flushing, abdominal cramps, myalgias, DIC, renal failure, cardiovascular collapse, and cardiac arrest. Clinically, the patient can present in shock. These reactions may be immediate, or there may be a delay of several hours before the symptom complex becomes apparent. Reaction to infusion of a unit of contaminated blood is most often distinguishable from an FNHTR by the former's more severe clinical presentation and from intravascular hemolytic transfusion reactions by the absence of characteristic hemoglobinuria and hemoglobinemia. Shock in a septic transfusion reaction is attributable to endotoxin produced by gram-negative bacteria. The presence of bacteria alone, however, can also cause many of these symptoms. The symptom complex often is attributable, in part, to cytokines and interleukins that are generated in vitro in the contaminated, stored blood. These biologic response modifiers produce severe reactions in vivo after transfusion.[3,7] For example, nitric oxide, produced locally in smooth muscle by the synergistic action of TNF-α, IL-1, and interferon-γ, probably mediates refractory hypotension and vasoplegia associated with septic shock.

If, during transfusion, a patient who appeared well suddenly develops rigors and shock, infusion of an infected component should be considered. If on further evaluation this diagnosis is still considered likely, the patient should be treated immediately, because delay significantly contributes to the chance of a fatal outcome. Blood pressure, heart rate, respirations, and renal blood flow need to be supported. Blood infusion should be stopped the moment any transfusion reaction is suspected, and appropriate samples should be sent to the blood bank for a DAT and other studies. Cultures of the untransfused blood remaining in the blood bag should be obtained because they may be diagnostic. Broad-spectrum antibiotics should be started immediately if infusion of contaminated blood is suspected and continued until the culture results are reported. Although these reactions are rare, they can be fatal. Because of the decrease in viral transmission by blood transfusion, septic transfusion reactions now account for a significant portion of the transfusion-related infections in the United States.[10] Data from the BaCon (Bacterial Contamination of Blood) study showed that from 1998 to 2000, the rate of transfusion-transmitted bacteremia was 9.98 per million single-donor platelets, 10.64 per million pooled platelets, and 0.21 per million RBC units; the rate of fatal reactions was 1.94 per million single-donor platelets, 2.22 per million pooled platelets, and 0.13 per million RBC units, respectively. To decrease the likelihood of a septic unit of platelets being transfused, the expiration date of units of platelet concentrate has been rolled back by the FDA, from a previously licensed 7-day storage period to the current licensed 5-day outdate. To further reduce the risk for bacterial transmission through platelet transfusion, the American Association of Blood Banks (AABB) mandated in 2004 that platelet concentrates be tested for bacterial contamination.[11] There are two bacterial detection systems approved by the U.S. Food and Drug Administration (FDA)[1] to be used for screening of blood components. Since the implementation of the mandatory bacterial testing for platelets, FDA data indicate that the mortality associated with septic transfusion reactions in the United States has dramatically decreased, although the risks for septic transfusion reaction have not been eradicated.

Transfusion Transmitted Diseases

With improvement of donor testing, especially NAT testing, the risk for transfusion-transmitted diseases has decreased dramatically. The current risks are approximately 1 : 1,900,000 for HIV, 1 : 137,000 for HBV, and 1 : 1,000,000 for HCV.[12] However, the risk is never zero. Moreover, there are emerging pathogens, such as babesiosis,[13] that may pose risks to the blood supply. It would be expensive and impossible to screen all potential pathogens to protect the blood supply. To improve blood safety, new technologies such as pathogen inactivation have been developed.[14,15] There are several platforms of pathogen-inactivation technologies. The principle of most pathogen inactivation is that agents added to blood components modify DNA or RNA templates, making them inaccessible to DNA or RNA polymerase, thereby inactivating pathogens (viruses, bacteria, and parasites) and also inactivating white blood cells. Pathogen-inactivation compounds that have been studied include alkylating compounds, binary ethyleneimine-like compounds, riboflavin, and methylene blue. Preclinical studies and phase III clinical trials have shown promising results in the efficacy and safety of pathogen inactivation agents. There are pathogen-inactivation systems approved for plasma and platelets in Europe. As of this date, the FDA has not licensed any pathogen inactivation technologies in the United States.

TRANSFUSION-RELATED ACUTE LUNG INJURY (NONCARDIOGENIC PULMONARY EDEMA)

Transfusion-related acute lung injury (TRALI), has become the leading cause of transfusion-related death reported to the FDA.[1,16] Even though TRALI represented 47% of reported fatalities to the FDA for the period of 2005 to 2010, the number of cases has continued to decrease in trend. The high percentage of TRALI cases may be alarming, but they are in part due to increased awareness of its clinical presentation. Symptoms of TRALI may range from mild dyspnea to severe noncardiogenic pulmonary edema, with symptoms and signs that include dyspnea, oxygen desaturation, respiratory failure, chills, fever, and hypotension. Most patients require oxygen support, and many may require mechanical ventilation. TRALI may develop within 1 to 6 hours of starting a transfusion and is not associated with an elevation in cardiac pressure.[16,17] The chest radiograph may reveal pulmonary edema pattern (bilateral infiltrates). In addition, there is respiratory insufficiency with decreased O_2 saturation, but without development of elevated left-side cardiac pressure. Copious amounts of fluid are produced in the lungs, as is

characteristic of hypervolemia; however, the noncardiogenic reaction usually follows infusion of volumes of blood too small to produce fluid overload. Silliman and associates[18,19] postulated that TRALI consists of a "two-hit" event, the first "hit" being a weakened underlying clinical condition that leads to the sequestration and priming of neutrophils in the lung tissue and the second being the transfusion of blood products containing human leukocyte antibodies (class I and II) that activate the neutrophils already present in the pulmonary parenchyma, leading to edema.[17] Complement and monocyte activation with aggregation of white blood cells also may occur when leukoagglutinins present in the recipient react with leukocytes contained in the infused donor blood. As a result of the HLA antigen-antibody reaction, the activated leukocytes express adhesive molecules on their surface (CD11/CD18), which then permit the leukocytes to attach to the cell membrane of the pulmonary endothelial cells and migrate to the interstitial space between the pulmonary capillaries and the alveolar epithelium. Once in the interstitial space, the neutrophils degranulate and through enzymatic digestion produce capillary dehiscence that results in fluid filling the alveolar sacs. Pulmonary leukostasis with pulmonary edema thus occurs as a result of microvascular occlusion and capillary leakage. Complement-activated granulocytes also produce oxygen radicals that damage pulmonary endothelial cells, resulting in a further increase in pulmonary vascular permeability and additional passage of fluid into alveolar spaces. Recently, it has been reported that aged blood products may accumulate bioactive lipids and soluble mediators, such as CD40L, that hamper the chemokine scavenging ability of erythrocytes as a result of reduction in the expression of the Duffy antigens, and this may represent a second hit in the two-hit model.[20] Rodent model systems for TRALI have also been described, and some of these models suggest a role for platelets in TRALI.[21] Work is ongoing in order to elucidate the different mechanisms leading to this symptomatology, which may be a final common pathway from a variety of initiating insults.

Because a definitive diagnosis of TRALI usually requires that cardiac monitoring (Swan-Ganz) catheters be in place, TRALI is difficult to diagnose outside the operating room or intensive care unit. When a patient shows signs of noncardiogenic pulmonary edema, the infusion should be immediately stopped, as it would be with all other reactions. These HLA/neutrophil antigen-antibody reactions may be idiosyncratic and often do not recur. Because of the inherent difficulty in differentiating TRALI from other competing diagnoses such as circulatory overload and the patient's underlying pulmonary status, efforts have been made to develop consensus guidelines to diagnose TRALI.[22]

The removal of leukocyte antigens from units of RBCs or platelets using leukocyte reduction filters may be helpful; and in other instances, washing RBCs may prove useful. Treatment is symptomatic (Table 120-3). Donors who are implicated in moderate to severe TRALI reactions should not be maintained as blood donors. In November 2006, the AABB made further recommendations to implement TRALI risk reduction.[23] It is, however, controversial regarding the optimal approach for TRALI risk reduction. Because their serum may contain high titers of leukoagglutinating antibodies, deferral of blood donors who are multiparous women and blood donors who have been transfused multiple times or have leukoagglutinating antibodies in serum has been used for TRALI risk reduction. This approach may be justified because TRALI reactions may originate when antibody titers are above certain threshold.[16] The exclusion of these donors may have merit since data continue to indicate that using male-only plasma leads to a significant reduction in TRALI cases.[24]

Table 120-3 Diagnosis of Transfusion-Related Acute Lung Injury

Onset	Within 6 hours of start of transfusion
Frequency	1:1000 to 1:4500 transfusions (probably underreported)
Signs and symptoms	Decreased O_2 saturation, fever, hypotension, tachypnea, dyspnea, diffuse pulmonary infiltrates, normal cardiac pressures (requires Swan-Ganz catheter), copious amounts of pulmonary edema fluid
Pathogenesis	HLA/granulocyte-specific antibodies (usually of donor origin) reacting with recipient leukocytes. Activates recipient neutrophils; stimulates complement activation; generates CD11/18 on the polymorphonuclear neutrophil surface, resulting in pulmonary capillary adherence and diapedesis and eventual pulmonary capillary leak syndrome. The latter is associated with generation of proteolytic enzymes and toxic O_2 metabolites, which cause endothelial cell damage. Neutrophil priming lipids may also play a role.
Diagnosis	Chest radiograph; blood gases; blood for HLA or antineutrophil antibodies
Differential diagnosis	Fluid overload; septic transfusion; anaphylaxis
Treatment	STOP TRANSFUSION! Provide ventilatory support (administer O_2, intubate as needed), support blood pressure, administer steroids; diuretics are of *no* value.

TRANSFUSION-ASSOCIATED CIRCULATORY OVERLOAD

Transfusion-associated circulatory overload (TACO) results from hydrostatic transudate accumulation in the lungs and should be considered in patients who, during a blood infusion, develop sudden onset of dyspnea, jugular venous distention, tachycardia, congestive heart failure, or other signs of fluid overload.[3] Unless a patient is actively hemorrhaging, blood should never be infused rapidly, because the acute expansion of a patient's intravascular volume may exceed the capacity of the cardiovascular system to compensate, resulting in fluid overload. Likewise, rapidly transfusing an anemic patient who is euvolemic and not actively bleeding produces no benefit and may cause harm. This caveat applies to transfusion of any blood component. Patients with compromised cardiopulmonary status may not tolerate acute blood volume expansion and may develop right- or left-sided heart failure. This is especially true for infants and the elderly. If symptoms occur, the transfusion should be stopped and the patient's blood volume reduced, either by diuretics or by phlebotomy. If there is a concern that the patient may not tolerate infusion of a full unit of blood or component within the 4-hour period allotted for infusion of blood components, the blood bank can divide the product into smaller portions, which can be transfused in aliquots. As a general guide, infusions in nonbleeding adults should occur at less than 2 to 3 mL/kg/hour. The rate should be lowered to 1 mL/kg/hour for patients at risk for fluid overload. Diuretics may be given to patients with compromised cardiopulmonary status before transfusion. Diagnostically, if the patient improves with diuretics, it is suggestive of TACO.

The initial stages of transfusion-induced hypervolemia may be difficult to distinguish from hemolytic transfusion reaction, FNHTR, allergic reaction, or TRALI. The absence of hemoglobinuria and hemoglobinemia and the absence of a positive posttransfusion DAT result should serve to distinguish the reaction from one caused by immune hemolysis. Likewise, the absence of fever, chills, or urticaria should help distinguish TACO from the febrile or allergic types of reactions. The clinical use of laboratory testing such as N-terminal pro-brain natriuretic peptide (NT-proBNP) may aid in the diagnosis; when NT-proBNP is elevated, it is highly sensitive and specific for TACO and makes other diagnoses in the differential much less likely.[25]

OTHER ADVERSE EFFECTS OF TRANSFUSION

Transfusion-Associated Graft-Versus-Host Disease

Transfusion-associated graft-versus-host disease (GVHD) occurs when immunologically competent lymphocytes are introduced into an immunoincompetent host who cannot destroy the donor lymphocytes. The immunocompetent donor lymphocytes engraft, recognize the host as foreign, and then attack host tissues. GVHD occurs after allogeneic bone marrow transplantation and, less often, after transfusion of nonirradiated cellular blood components, especially when the blood donor and recipient share some HLA antigens.[3] There is an increased danger from posttransfusion GVHD, in part because of the frequent failure of physicians to recognize the risk. Another major factor, however, is the propensity of the donor's lymphocytes to produce recipient bone marrow aplasia. In GVHD after bone marrow transplantation, the bone marrow is of donor origin, and bone marrow aplasia does not occur. In posttransfusion GVHD, however, the donor's lymphocytes attack the bone marrow of recipient/host origin, producing aplasia.

Posttransfusion GVHD is fatal in more than 90% of cases, primarily because of aplasia of the recipient's bone marrow. It may occur 8 to 10 days after transfusion with a marked pancytopenia, as well as multiorgan involvement of GVHD such as skin and liver. The signs and symptoms include nausea, vomiting, anorexia, fever, watery diarrhea, liver dysfunction, and rash. Patients often die of infection and bleeding within 3 to 4 weeks. There is no effective treatment, with the possible exception of bone marrow transplantation, if posttransfusion GVHD is recognized early and if a suitable donor can be found in a short time. Reports have shown that haploidentical directed donor units of blood may produce fatal posttransfusion GVHD even in immunocompetent recipients. The use of irradiated blood (2500 cGy) is thus recommended in clinical situations in which posttransfusion GVHD is considered likely, such as when patients receive directed blood transfusions from their relatives. Leukocyte-reduction filters should not be used as prophylaxis against GVHD, because the exact number of leukocytes needed to produce the disease is not known with certainty. Case reports of fatal GVHD in patients who received leukoreduced, but not irradiated, blood have been published. Several articles have addressed this subject. Irradiation of RBCs produces a membrane defect, however, which causes slow leakage of potassium and hemoglobin. Accordingly, the FDA ruled that irradiated units of RBCs shall have an outdate not to exceed 28 days from the time of irradiation. GVHD continues to be a rare but extremely serious complication of blood transfusion. Although it is controversial, prophylactic irradiation is usually not indicated for patients with human immunodeficiency virus (HIV) infection (see box on Risk Groups for Transfusion-Associated Graft-Versus-Host Disease).

Risk Groups for Transfusion-Associated Graft-Versus-Host Disease

Risk Well Defined
- Congenital T-cell defects (known or suspected)
- Immunologic immaturity (fetus or premature infant)
- Intrauterine transfusion
- Neonates undergoing intrauterine exchange transfusion or extracorporeal membrane oxygenation
- Acquired T-cell defects
- Bone marrow or peripheral blood stem cell transplant recipients (allogeneic or autologous)
- Hodgkin disease
- Haplotype sharing between donor and recipient
- Transfusions from blood relatives
- HLA-matched platelets

Risks Identified but Not Clearly Defined
- Hematologic malignancies (other than Hodgkin disease)
- Solid tumors
- Immunologic immaturity or prematurity (in the context of small-volume transfusion)
- Certain immunosuppressive agents such as fludarabine

Risks Not Identified
- Acquired immunodeficiency syndrome (AIDS)
- Aplastic anemia (except in setting of bone marrow transplantation or immunosuppressive therapy)

Posttransfusion Purpura

Posttransfusion purpura (PTP) is a rare and self-limiting thrombocytopenia occurring 5 to 10 days posttransfusion in patients lacking a specific platelet antigen, usually PLA1 (HPA-1a).[3] These patients often have a history of sensitization with prior transfusions or pregnancies. After resensitization by the transfusion, patients can develop potent antibodies against the platelet-specific antigen that they are lacking but which is present on donor platelets. These platelet antibodies often have a high titer and can fix complement. As a result, the transfused platelets and the patient's own platelets are also destroyed through the adsorption of the antigen or immune complexes on their own platelets. A concurrent autoimmune process may also involve destruction of the recipient's own platelets, as shown in one case report of a positive antibody against the patient's own platelets. The thrombocytopenia can be marked with a platelet count falling below 10,000/μL. The onset is sudden, although self-limited, and usually resolves in 2 weeks. Intravenous immunoglobulin (IVIg) appears to be an effective treatment, although plasma exchange, steroids, and splenectomy can also be useful. Patients with acute bleeding and needing platelet support should receive platelets without the platelet-specific antigen, if at all possible. If random donor platelets are given, patients can develop severe reactions, including allergic reactions. Recurrence of PTP is rare.

Hypothermia

Hypothermia can occur with rapid infusion of large quantities of refrigerated (1° C-6° C) blood, such as in cases of rapid and massive transfusions.[3] Data have shown that rapid infusion of blood (1 unit every 5 minutes) may lower the temperature of the sinoatrial node to less than 30° C, at which point ventricular fibrillation may occur. Use of warming devices for some trauma patients may reduce the incidence of coagulopathies associated with major trauma and also help to overcome cardiac complications. Most transfusions need not be given this rapidly. For routine transfusion, blood does not have to be warmed. Indeed, overwarming a unit of blood can cause RBC thermal injury and produce hemolysis, DIC, or shock.

If blood is to be warmed, the temperature must be monitored and kept below a level that could cause hemolysis. Usually, this is less than 42° C. Heating blood under running hot tap water or heating in a microwave device is unacceptable; microwave devices produce hot spots that can cause hemolysis.

Electrolyte Toxicity

Citrate, a component of the preservative solution used in blood storage, functions as an anticoagulant by chelating calcium and interfering with the coagulation cascade.[3] Rapid transfusion of citrated blood can be associated with a drop in ionized calcium levels. Citrate-containing blood products, however, are routinely infused without any problem, because the citrate is rapidly metabolized to bicarbonate. In patients with normal liver function, citrate infusion is very unlikely to produce reactions. Mild to severe citrate toxicity can be seen, however, in individuals undergoing therapeutic apheresis when large volumes of citrated RBCs or plasma are reinfused.

The effects of hypocalcemia range from mild circumoral paresthesias to frank tetany. However, severe citrate toxicity, even with massive transfusion, is very rare. More commonly, the reaction is mild and self-limiting and can be treated by merely slowing the rate of reinfusion. If prolonged QT intervals or signs of tetany are seen, calcium can be administered. Infusion of calcium itself, however, may be associated with the development of ventricular arrhythmias and cardiac arrest. Calcium need not be infused routinely, even after large-volume blood transfusions. However, it may be prudent to monitor calcium status in patients undergoing massive transfusion and at risk for hypocalcemia due to citrate toxicity. Under no circumstances should calcium be added to a unit of blood, because it would recalcify the unit and cause clots to form in the bag. In patients with signs of hypocalcemia associated with infusion of citrate, such as in apheresis, correction of the hypocalcemia often requires infusion of magnesium, as well. Signs of hypocalcemia are often better treated with intravenous calcium infusion, because oral calcium carbonate supplements may be ineffective. In addition to the effects on calcium, the metabolism of citrate also can result in a metabolic alkalosis due to the generation of large amounts of bicarbonate.

Hypomagnesemia, presumably due to chelation of magnesium by citrate, has also been reported. Actual clinical complications of transfusion-induced hypomagnesemia, however, have not been well documented, other than in the cases of cytapheresis.

Hyperkalemia due to infusion of stored blood is a rare occurrence. Although hyperkalemia is often thought to be a problem in massive transfusion, in reality development of hypokalemia is of greater concern. With storage, leakage of potassium from RBCs to the extracellular fluid occurs. However, after infusion, the RBCs reverse the biochemical storage lesion by restoring the Na-K ATP membrane pump, and intracellular potassium levels are restored. As the citrate is metabolized to bicarbonate, the blood becomes alkalotic, contributing to hypokalemia. In massive transfusion, it is not uncommon for this to result in the need for administration of potassium. Extracellular potassium increases at the rate of approximately 1 mEq/day during the first few weeks of storage. If this presents a concern for neonates or patients with renal failure, fresher or washed blood can be requested. As there is increased potassium leakage from RBCs after exposure to 25 Gy of radiation to prevent posttransfusion GVHD, a maximum 28-day shelf life from the day of irradiation is imposed on this blood component.[11] Ammonia toxicity, previously a concern with stored blood, rarely presents problems.

Iron Overload

One milliliter of red blood cells contains 1 mg of iron. A unit of blood with 250 mL of RBCs thus contains approximately 250 mg of iron, and 4 units of blood contain 1 g of iron, roughly the amount stored in the bone marrow. Men and nonmenstruating women lose only approximately 1 mg of iron each day. Continued use of transfusion therapy in individuals with an extravascular type of hemolytic anemia, such as those with thalassemia or sickle cell anemia, in which iron is not lost from the body but is recycled, can thus result in the accumulation of excessive tissue stores of iron. Over long periods, the iron that is stored in parenchymal cells results in death of the cell and eventual organ failure.[26] Iron chelation therapy, such as that with deferoxamine, is now widely used and is often able to maintain patients with chronic hemolytic anemia in negative iron balance. The availability of oral iron chelaters such as deferasirox and deferiprone provides an alternative mode of iron chelation therapy.[27]

Air Emboli

Since the replacement of evacuated glass bottles by plastic blood bags, the risk for air embolism from phlebotomy or transfusion has virtually disappeared from transfusion practice. Air, however, still may be pumped into patients by the roller pumps contained in various transfusion devices, especially apheresis machines and intraoperative salvage machines.[28] All such devices currently manufactured, however, contain air-in-line sensors. However, any operators using this equipment must be well trained and remain alert to the potential risk for air embolization at all times while the patient is being treated. Patients who receive air intravenously experience acute cardiopulmonary insufficiency. The air tends to lodge in the right ventricle, preventing blood from entering the pulmonary circulation. Acute cyanosis, pain, cough, shock, and arrhythmia may occur, and death may result unless immediate action is taken. The patient should be placed head-down on the left side; this usually displaces the air bubble from the pulmonary valve. Use and removal of central lines may also pose a risk for air embolism.

Complications Associated With Massive Transfusion

Patients requiring massive transfusion (frequently defined as the transfusion of one whole blood volume within a 12- to 24-hour period of time) are critically ill with multiple medical issues. Common problems associated with massive transfusion include coagulopathy, hypothermia, and metabolic abnormalities; hypothermia and metabolic abnormalities are discussed earlier in this chapter.

Coagulopathy of massive transfusion is a multifactorial hemostatic disorder that can have devastating consequences.[29,30] Classically, the coagulopathy associated with massive transfusion was thought to be attributable solely to consumption of factors due to ongoing hemorrhage and/or dilution due to the large volume of fluids and RBCs typically infused. However, the understanding of hemostasis in massive transfusion has recently expanded to include a form of coagulopathy that occurs *before* coagulation factors and platelets are consumed. This so-called early coagulopathy, described primarily in the setting of trauma, is driven by tissue hypoperfusion and increased fibrinolysis.[29] Early coagulopathy is not likely to respond to traditional transfusion therapy and may only be resolved with restoration of circulatory capacity and inhibition of fibrinolysis.

Despite enhancements in our understanding of early coagulopathy, platelet/coagulation factor dilution and consumption still remain outstanding problems in the setting of massive transfusion. Patients undergoing large-scale transfusion must be regularly monitored for hematocrit, platelet count, prothrombin time/INR, partial thromboplastin time, and fibrinogen. Reasonable goals to promote hemostasis in the setting of massive transfusion are to maintain (1) Hct >25%, (2) platelets >50,000 /μL, (3) INR <1.7, and (4) fibrinogen ≥100-150 mg/dL.[29,30] Therefore it is imperative that clinicians provide more than just RBCs to their massively bleeding patients. To better ensure a more appropriate provision of plasma and platelet products, many facilities have developed rigorous protocols consisting of preset numbers of RBC, FFP, and platelet units that are immediately issued upon requests for massive transfusion. Such protocols, developed in conjunction with surgical and trauma services, can drastically improve blood product provision and outcomes in the setting of massive transfusion. Although massive transfusion protocols are useful tools to combat coagulopathy, there remains much controversy regarding the numbers of plasma and platelet products that should be provided to patients transfused with large volumes of RBCs. Trials and reports from military trauma centers have promoted use of massive protocols based around a 1:1:1 ratio of RBC units:plasma units : platelets. Data from combat theaters suggest that such ratios are successful in avoiding the coagulopathy of massive transfusion and ultimately lead to improved survival.[31] Despite these data, it is unclear whether such approaches are relevant to noncombat, civilian hospitals, which frequently issue massive transfusions for wide-ranging indications such as surgical complications, large gastrointestinal or retroperitoneal hemorrhages, or blunt trauma.[32]

Complications Associated With Hematopoietic Progenitor Cell Infusion

Hematopoietic progenitor cells (HPCs), the most widely used cell therapy products, may be derived from bone marrow, peripheral

blood, and cord blood. As with regular blood transfusions, the infusion of HPCs carries the risk of the same typical types of transfusion reactions. However, additional risks are associated with HPC infusion, such as those related to the cryopreservatives used and the complex cellular components collected.[3] For many reactions, it may be difficult to identify the causative agent. Moreover, because of the often-irreplaceable nature of HPC products, higher infectious risks may be unavoidable. Only those reactions that are unique or more problematic for HPC infusions are discussed in this section. See Table 120-4 for summary.

DMSO Toxicity

The most common reactions to HPC have been attributed to dimethyl sulfoxide (DMSO), the most widely used cryopreservative.[3,33] A variety of symptoms may be associated with DMSO infusion. A garlic odor commonly accompanies DMSO infusion, and nausea and vomiting are often reported with DMSO-cryopreserved HPC infusions. Additional DMSO-related symptoms include flushing, coughing, chest tightness, dyspnea, abdominal pain, hypotension, hypertension, cardiac toxicity (such as bradycardia and other arrhythmias), and rarely, neurologic toxicity (such as syncope and transient encephalopathy). Some cases of DMSO toxicity are thought to be due to the release of histamine. Agents such as diphenhydramine have been used for the treatment and prevention of DMSO-related toxicity. Antiemetic agents such as prochlorperazine have been useful for ameliorating nausea and vomiting. Most clinical services have protocols in place to limit the volume of DMSO that can be infused, such as setting an upper infusion limit of 1 g/kg/day, dividing HPC infusion doses, or washing HPC products to remove DMSO (this, however, may result in cellular loss).

RBC Engraftment and Hemolysis

Although ABO and non-ABO blood groups are not obstacles to successful HPC transplantation, these antigens (and their corresponding antibodies) do create some problems during the transplant period. When considering incompatibilities within the ABO system, three scenarios are possible: (1) antibodies present in the recipient that interact with incompatible cells present in the graft (major incompatibility), (2) antibodies present in the plasma-portion of the graft that mediate hemolysis of recipient RBCs (minor incompatibility), or (3) antibodies present in both the recipient and the donor that may interact with incompatible RBCs (bidirectional, or two-way, incompatibility).[3] It has been previously shown that both major and bidirectional ABO incompatibility can result in delayed progenitor cell engraftment. In such cases, it is postulated that anti-ABO antibodies may mediate a suppressive effect on RBC precursors expressing these antigens, leading to reticulocytopenia and prolonged anemia. In the most severe form of this process, HPC recipients can develop pure RBC aplasia, a condition wherein bone marrow shows a virtual absence of immature erythroid elements more than 3 months posttransplantation. In cases of either delayed engraftment or pure RBC aplasia, patients are often dependent on RBC transfusions for prolonged periods of time in order to maintain adequate oxygen-carrying capacity.

Another risk factor associated with HPC infusion is the possibility for RBC hemolysis. Both ABO and non-ABO antibodies are capable of mediating RBC lysis. In such conditions, preformed antibodies in either the recipient or HPC plasma can cause accelerated clearance of incompatible RBCs by either intra- or extravascular mechanisms. Presentation of hemolytic transfusion reactions immediately after HPC infusion is no different from that of typical transfusion reaction. Policies and protocols should be in place to prevent postinfusion HPC-related hemolysis—for example, plasma depletion of HPC products (in cases of minor mismatch and bidirectional ABO incompatibility), limiting the infusion of incompatible RBCs (in cases of major mismatch and bidirectional ABO), hydration of patients, and others.

Although delayed hemolysis is rarely clinically significant in major ABO mismatched HPC transplant, clinically significant delayed hemolysis is commonly reported in minor and bidirectional ABO-incompatible HPC transplants. As a result of donor lymphocyte engraftment, typically occurring 1 to 2 weeks after HPC infusion, donor ABO antibodies can cause hemolysis of residual recipient RBCs. This delayed hemolysis is typically clinically evident with decreased hemoglobin, increased indirect bilirubin, increased LDH, and decreased haptoglobin, and patients often require RBC transfusion. Sometimes, the hemolysis can be massive and result in multiorgan failure and death. Thus it is important to monitor patients for hemolysis after minor and bidirectional ABO incompatible HPC infusion. Timely support and treatments such as RBC exchange can be provided for massive hemolysis if it occurs.

Infectious Complications

As a result of an underlying bacteremia during collection, or contamination through collection, processing, storage, thawing, and sampling, some HPC products may harbor microbial organisms

Table 120-4 Common Hematopoietic Progenitor Cell Infusion Reactions

Types	Presentations	Treatment and Prevention
DMSO toxicity	Halitosis, nausea, vomiting, flushing, coughing, chest tightness, dyspnea, abdominal pain, hypotension, hypertension, cardiac toxicity (such as bradycardia and other arrhythmias), and rarely neurologic toxicity, such as syncope and transient encephalopathy	Antihistamine Antiemetics Limiting DMSO infusion volume
ABO mismatch	Hemolysis at the time of infusion Delayed RBC engraftment (major mismatch and bidirectional) Delayed hemolysis (minor mismatch and bidirectional)	Plasma depletion of HPC products (in cases of minor mismatch and bidirectional ABO incompatibility) Limiting the infusion of incompatible RBC (in cases of major mismatch and bidirectional ABO) Hydration of patients Other supportive care if necessary RBC transfusion support Monitor for RBC engraftment Modify immunosuppression RBC transfusion support Monitor for hemolysis Hydration, RBC exchange, and other supportive care if massive hemolysis

capable of mediating septic reactions during or immediately after HPC infusion.[2] Such reactions may manifest with high fever, tachycardia, hypotension, nausea, or vomiting and, in severe cases, can progress to a shock-like state. Patients experiencing such symptoms should be treated with broad-spectrum antibiotics to cover both gram-positive and gram-negative organisms.[34] Transfer of the patient to an intensive care setting is also prudent because mechanical respiration and additional supportive measures (e.g., pressors) may be necessary to prevent a cardiovascular collapse.

Fortunately, the bacterial contamination of an HPC unit is often known well in advance of an actual HPC infusion. This is because many HPC products are cultured at the time of collection and processing. As such, clinical teams can be well-prepared for such reactions. In such circumstances, preventative measures include provision of preinfusion antibiotics to cover the documented organism(s) and close patient surveillance during and after infusion. The infusion of the product in a monitored setting may be warranted. One additional option would be to avoid infusion of a contaminated unit altogether. This is possible if a patient has multiple, separate HPC products available for infusion. Clinical and transplant teams can preferentially infuse noncontaminated HPC units first, saving the contaminated unit as a "last resort" should the graft fail.

Other Infusion Complications Related to HPC Products

In addition to the problems related to DMSO and ABO mismatches, other adverse reactions sometimes occur with the use of HPC products.[3] Nausea and vomiting are frequently reported with infusion of freshly collected HPC products such as fresh marrow. Fever and chills are commonly seen with cryopreserved HPC; these have been speculated to be caused by the cellular debris and cytokines contained in HPC products. Antipyretics and steroid premedication may be used for prevention. Severe adverse reactions to HPC infusion (such as cardiac arrest and neurologic symptoms, including loss of consciousness and seizure) have been linked to high granulocyte counts in HPC products.

Respiratory problems are increasingly being recognized as an important cause of morbidity and morality in the setting of HPC infusion. Although many of these are late-onset problems (e.g., infectious complications associated with immunosuppression occurring days or weeks after transplantation), some pulmonary issues will arise acutely during HPC infusion. The National Marrow Donor Program (NMDP) issued a report in 2010 regarding seven patients who experienced hypertension, chest pain, and decreased oxygen saturation after infusion of cord blood.[35] Even though no clear cut cause-effect relationship was established, some recommendations were made, including minimizing thaw to infusion time, filtering HPC products with standard 150-250 micron blood filters, avoiding very high infusion rate, and others. In addition, the classic pulmonary complications encountered during HPC infusion may resemble TRALI in that they are typically associated with dyspnea, hypoxemia, a low-grade fever, and bilateral pulmonary infiltrates, all occurring within a short time after initiation or completion of infusion. Some authors have attributed these problems to a noncardiogenic capillary leak syndrome that appears to be independent of cardiac function, similar to the proposed pathophysiology of TRALI.

Patients demonstrating signs or symptoms of respiratory distress during HPC infusion must be treated aggressively. The first response should be to stop the HPC infusion and provide immediate respiratory support in the form of oxygen. If the patient does not recover with these measures, or if the situation worsens, then consideration may be given to intubation to prevent respiratory failure. The provision of corticosteroids or other immunosuppressive agents is not likely to be of benefit for such reactions. It may also be prudent to investigate whether the patient's symptoms are related to circulatory overload rather than arising from noncardiogenic pulmonary edema. This distinction may be accomplished by measuring plasma levels of brain-natriuretic peptide (BNP). If BNP is elevated, then the patient's symptoms may be attributable, in part, to volume overload and a trial of diuresis is likely warranted.

National Healthcare Safety Network

The National Healthcare Safety Network (NHSN) is a national program of combined governmental and private sector agencies designed to evaluate and track transfusion reactions and other adverse effects associated with infusion of blood products and derivatives. Similar programs exist in other countries, including the United Kingdom and France. The Hemovigilance Module, the first protocol release of the Biovigilance Component of NHSN, was developed through a public-private partnership between the Centers for Disease Control and Prevention (CDC) and subject matter experts convened by AABB. The Hemovigilance Module is designed for transfusion services staff in health care facilities to monitor recipient adverse reactions and quality-control incidents related to blood transfusion.

The Hemovigilance Module provides standard criteria and definitions to participating facilities to report adverse events related to blood transfusion that will result in aggregate data suitable for trend analyses and benchmarking. Participating facilities can analyze their data independently within NHSN and will be able to compare their data with national aggregate rates in a confidential manner through NHSN in the future.

The following transfusion reaction categories are used to identify types of adverse events related to blood transfusion:

- Allergic
- Acute hemolytic
- Delayed hemolytic
- Delayed serologic
- Febrile nonhemolytic
- Hypotensive
- Posttransfusion purpura
- Transfusion associated circulatory overload (TACO)
- Transfusion-associated dyspnea
- Transfusion-associated graft versus host disease
- Transfusion-related acute lung injury (TRALI)
- Transfusion-transmitted infection

Transfusion reactions are further classified by their severity and imputability—that is, the likelihood that the reaction is attributable to infusion of the blood product being investigated. Protocols, forms, and enrollment information are available online (http://www.cdc.gov/nhsn/bio.html).

CHAPTER 121

TRANSFUSION-TRANSMITTED DISEASES

Louis M. Katz and Jay E. Menitove

Adverse reactions following blood transfusion reflect immunologic, pathophysiologic, and microbiologic events. This chapter presents information about transfusion-associated viral, bacterial, parasitic, and prion infections and emerging agents. Transfusion-transmitted infection risk mitigation through blood donor screening and blood testing strategies are presented.[1] The box discussions provide insights into interventions aimed at reducing risk from known and emerging threats and new technologies for reducing or eliminating microbial contamination. Red cell, platelet, and plasma transfusion represent important therapeutic modalities for appropriately selected patients. Awareness of the hazards of transfusion and the rate at which these events occur should enable physicians to better determine the benefit : risk ratios when prescribing transfusions.

HEPATITIS VIRUSES

The hepatitis viruses can be classified according to their predominant modes of transmission, parenteral and enteric, with the parenterally transmitted agents, hepatitis B virus (HBV) and hepatitis C virus (HCV) dominating concerns about transfusion transmission because many individuals unknowingly infected with these agents become asymptomatic chronic carriers and may make blood donations.

Hepatitis B

HBV is a deoxyribonucleic acid (DNA) virus in the family Hepadnaviridae. The infective virion is known as the Dane particle and has surface and core components, surface antigen (HBsAg) and core antigen (HBcAg), respectively. Epitopes on the viral surface provide a basis for epidemiologic studies and consist of the HBsAg "a," d/y, and w/r determinants. Recombinant vaccines containing the "a" determinant confer protective immunity to a high proportion of vaccinees and are dramatically altering the incidence and prevalence of HBV infection in the general population where they are in wide use and consequently in the donor population.

The average incubation period (the time from infection to liver enzyme elevation and symptomatic hepatitis) is 59 days (range, 5 to 12 weeks) but may be as long as 6 months. Symptoms, which occur in 30% to 50% of infected persons age 5 years and older, include fatigue, anorexia, nausea, vomiting, jaundice, dark urine, light stools, arthralgias, rashes, vasculitis, and glomerulonephritis. The risk for progression to chronic infection is inversely related to age at infection. HBV infection becomes chronic in more than 90% of infants, 25% to 50% of children 1 to 5 years of age, and less than 5% of older children and adults. Approximately 5% of the U.S. population has serologic evidence of prior HBV infection (antibodies against HBcAg [anti-HBc] reactive). From the mid-1980s through 2008, with increasing immunization in early childhood, the incidence of acute HBV infection has fallen nearly an order of magnitude from more than 11 cases per 100,000 to 1.3. There were an estimated 800,000 to 1.4 million U.S. residents with chronic HBV infection in 2006.

Based largely on data from parenteral exposures of health care workers, HBV is 100 times more infective than human immunodeficiency virus (HIV) and 10 times more infective than HCV. The predominant mode of transmission to adults and adolescents is through sexual contact. Forty percent have infected partners, 15% are males having sex with other males, injecting drug users account for 14% of cases, and one-third have no identifiable risk.

HBsAg is detectable in blood approximately 4 weeks (30 to 60 days) after infection. Subsequently, immunoglobulin M (IgM) anti-HBc antibodies appear coincident with symptom onset. High viral titers (10^{10} genomes/mL) present at that time decline subsequently. HBsAg persists transiently in acute infections for up to 4 months (average 63 days). Antibodies against HBsAg (anti-HBs) develop subsequently and protect against reinfection. Some anti-HBc–positive and anti-HBs–negative carriers have circulating HBV DNA, and this pattern defines so-called occult HBV infection. Although anti-HBs confers immunity to reinfection, sufficient virus remains in the liver to transmit HBV following liver transplant from anti-HBs–positive donors and to cause reactivation under intense immunosuppression.

Blood donors in the United States are queried for a history of hepatitis and risks associated with hepatitis and screened for HBsAg and anti-HBc. The use of HBV nucleic acid testing (NAT) in minipools, though not required as of mid-2011, is nearly universal. The risk for HBV transmission per unit in the United States was 1 per 280,000 to 355,000 donations using very sensitive HBsAg testing and is only modestly decreased with minipool NAT (Table 121-1).[2,3] Most contemporary HBV transfusion-transmitted infections are attributable to blood donations from asymptomatic donors during acute infection preceding the development of detectable HBsAg. During this "window period," HBV replicates relatively slowly with a doubling time of HBV viral load of approximately 2.6 days. Rare cases are due to HBV variants not detectable by HBsAg testing. With current routine testing for HBsAg and anti-HBc, the addition of HBV NAT in minipools will have a small impact on residual HBV risk because contemporary HBsAg tests approach the sensitivity of minipool NAT. Among 3.7 million blood donors to the American Red Cross during 2008, 1 per 6028 were infected with HBV. Of these, 604 had positive HBsAg, with or without HBV DNA (1 per 6117), and only 9 were identified solely by NAT in minipools (1 per 410,540). NAT on individual donation aliquots has the potential to reduce the risk for transfusion-transmitted HBV further by detecting newly infected donors slightly earlier than the HBsAg tests licensed for blood donor screening. The costs of performing individual donation NAT for HBV, combined with declining HBV incidence associated with population-based vaccination and the low rate of clinical morbidity in most transfused populations, suggest it is not cost-effective by usual criteria.

Manufacturers of NAT donor screening assays have now included HBV DNA in Food and Drug Administration (FDA)–licensed multiplex platforms (with HIV and HCV), eliminating an important operational barrier to its implementation, leading to widespread use. The Blood Products Advisory Committee at FDA endorses the use of HBV DNA testing, although there has been no formal guidance from that agency at the time of this writing.

There is evidence that some HBsAg assays will not detect all S gene variants of HBV. Donors in the United States are screened universally for both HBsAg and anti-HBc, and increasingly with NAT; this makes it likely that a mutant strain of HBV would be

Table 121-1 Risk for Transfusion-Transmitted Diseases in the United States

Pathogenic Agent or Disease	Average Estimated Risk Per Unit
Hepatitis A	Rare
Hepatitis B	<1/350,000-1/470,000 (assuming MP NAT implemented)
Hepatitis C	1/1,935,000
Human immunodeficiency virus	1/1,467,000
Human T-lymphotropic viruses 1, 2	1/2,400,000
Cytomegalovirus	Infrequent
Parvovirus B19	Rare
West Nile virus	Rare
Malaria	3 cases per year
Babesiosis	>160 transfusion-associated cases reported
Chagas disease	Rare
Creutzfeldt-Jakob disease	4 vCJD transfusion-associated cases reported
Bacterial contamination:	
Red cells	1/30,000
Septic reaction	1/500,000-1/10,000,000
Platelets	1/3000-1/8000
Septic reaction	1/15,000-1/100,000
Emerging infections: Dengue virus Chikungunya virus Pandemic influenza viruses (see Dengue, in text, for added language on pandemic flu) (H5N1, H1N1)	Risk unknown

MP, Minipool; *NAT,* nucleic acid test; *vCJD,* new variant Creutzfeldt-Jakob disease.

detected in the United States. An exception might be an individual with an S gene variant who presents in the early stages of acute hepatitis before the development of anti-HBc, although NAT should detect all these donors.

Hepatitis D

Hepatitis D Virus (HDV) was originally called the delta agent. It is a defective ribonucleic acid (RNA)–containing passenger virus that requires active synthesis of HBsAg to act as a "helper" for assembly of HDV virions. As many as 10% of HBV infections are accompanied by HDV worldwide. Its prevalence is very low in the United States but higher in injection drug users. HDV superinfection of chronic HBV carriers is associated with worsened chronic sequelae and with fulminant hepatitis. Screening for HBV acts synergistically to prevent transfusion-associated HDV cases by identifying donors that are coinfected with HBV and HDV.

Hepatitis C

HCV is an RNA virus in the family Flaviviridae, genus Hepacivirus There are six genotypes that share similar epidemiology, pathogenesis, and natural histories. In the United States, genotypes 1, 2, and 3 cause 75%, 10%, and 10% of infections, respectively. Genotype 1 responds relatively poorly to traditional treatment regimens using interferon and ribavirin compared with 2 and 3, but recent approval of HCV protease inhibitors promises to improve these rates. HCV is distinguished by a low rate of recognized acute infection and by a high rate of chronic infection, with substantial morbidity and mortality over long periods of observation as a result. In the United States there are an estimated 3.2 million chronic infections.

The most common source of HCV acquisition is injection drug use. The prevalence of HCV in U.S. adults (20 to 59 years old) with any history of illicit injection drug use is greater than 45%. Other risks include blood transfusion before donor serologic screening began in 1990, a high lifetime number of sex partners, and exposure in health care settings, including through dialysis. Fifteen percent to 30% of patients report no risk factors in large series. Vertical transmission occurs to 3% to 7% of infants of mothers with active infections. In contrast to HBV, sexual transmission is an inefficient route of infection, but was found to be the most likely mode of transmission of HCV among HIV-infected men who have sex with men in New York City. Among blood donors, 0.072% have confirmed positive HCV test results.

At most 20% to 30% of newly infected persons develop recognizable symptoms during acute HCV infection. Chronic infection develops in 75% to 85% of persons infected after 45 years of age and in 50% to 60% of those infected as children or young adults. Chronic HCV infection progresses to cirrhosis in 15% to 30% over 30 years of observation. Hepatocellular carcinoma occurs in 1% to 4% per year in those with cirrhosis. HCV is among the most prevalent causes of chronic hepatitis, cirrhosis, and primary liver cancer in the developed world and is the most common indication for liver transplantation in the United States, resulting in around 2400 procedures annually.

The risk for posttransfusion HCV infection declined progressively with the introduction of surrogate markers for non-A, non-B hepatitis in the 1980s (alanine aminotransferase and anti-HBc) and of serologic testing for HCV antibodies in May 1990, followed sequentially by improved serologic testing and NAT. The seronegative-window period for the first-generation HCV antibody test extended to 6 months from infection, but was reduced to 82 and 70 days with second- and third-generation assays, respectively. NAT further reduced the window period to 10 to 25 days. The risk per unit declined from an estimated 1 per 276,000 units to 1 per 1,935,000 units, and residual risk estimates from the incidence-window period model using serologic data have been confirmed using NAT.

NAT is labor and resource intensive, so HCV NAT deployment was dependent on the use of so-called minipools, created by combining aliquots from 16 to 24 donations (currently 6 to 16). Loss of test sensitivity due to sample pooling was tolerable given the rapid increase or burst of HCV viremia before antibody seroconversion (estimated doubling time of 10.8 hours in that period) and the high titer of viremia during the 40- to 50-day plateau phase preceding antibody seroconversion. Although minipool NAT has been implemented successfully and with moderate yield in many developed countries, it is expensive and its cost-effectiveness low in comparison to other medical interventions.

As an alternative to NAT assays, enzyme immunoassays (EIAs) have been developed that detect HCV core antigen in serum or plasma, either as an individual analyte in parallel with antibody assays or as HCV antigen-antibody combination assays. These tests reduce the preseroconversion-window period and are being adopted in some developing countries. They are less sensitive than HCV NAT and are not approved for blood donor screening in the United States.

The remarkable advances in safety achieved by the introduction and successive improvements in the clinical sensitivity of HCV assays have greatly reduced transfusion-associated HCV cases. Nonetheless, some newly infected individuals demonstrate fluctuations in HCV RNA, at times below NAT detection thresholds before antibody seroconversion. This likely explains some of the low residual risk for transfusion-transmitted HCV infection despite the ongoing combination of HCV antibody and RNA testing.

The seroprevalence of HCV, the prolonged interval between infection and clinical manifestations, and the relatively high rate of HCV clinical sequelae prompted blood collection facilities and hospitals to conduct "look-back" notification of previous recipients of blood given by donors found on subsequent donations to be HCV infected. Look back was subsequently made mandatory in companion rules from FDA and the Centers for Medicare and Medicaid Services. In general, HCV look-back programs found half or fewer of targeted transfused individuals alive, but were able to find both seropositive and RNA-positive recipients who were unaware of their status. In one study the cost to find a seropositive recipient who was unaware of his or her infection was $3146.

Hepatitis A

The hepatitis A virus (HAV), a nonenveloped picornavirus, is transmitted predominantly by the fecal-oral route, with an average incubation period of 28 days (range, 15 to 50 days) with signs or symptoms persisting for less than 2 months. The incidence of HAV infection in the United States fell by 76% from the period 1990 to 1997 to 2003 after the recommendation for targeted immunization of members in high-risk communities. Populations at risk include those in areas where extended community outbreaks occur and children living in states that have high and intermediate rates of disease, staff and residents of closed communities, close personal contacts of cases, the staff and parents of children in day-care centers and those with common-source exposure to infected food or water. For many sporadic cases there is no recognized source. HAV is self-limited with no chronic carrier state, but approximately 10% to 15% of infected individuals develop a more prolonged or relapsing illness. It is the most frequent cause of hepatitis among children under 11 years of age.

Transfusion-related transmission, although rare, is due to a blood donation from a recently infected, asymptomatic, viremic individual. The peak viremia occurs 2 weeks before onset of jaundice or elevation of hepatocellular enzymes and persists for a median period of 42 days (range, up to 59 days). The virus is quite resistant to many inactivation procedures, including the pathogen-reduction procedures being developed for cellular blood components (e.g., psoralens or riboflavin, both with ultraviolet [UV] irradiation) and fresh-frozen plasma (solvent/detergent and methylene blue). Transmission by clotting-factor concentrates treated with the solvent/detergent pathogen-reduction process occurred in the 1990s, and low risk persists despite the lack of HAV infection among hemophilia patients treated in the early 2000s.

An indefinite deferral for a clinical history of viral hepatitis after age 11 years is required in the United States (regardless of the specific viral agent). Because most viral hepatitis in the United States before 11 years is HAV, with its relatively brief and self-limited viremia, individuals with a history of hepatitis before the age of 11 are allowed to donate on the assumption they had HAV. A 120-day deferral is recommended after exposure to HAV during community outbreaks to prevent transfusion transmission. In vitro screening for HAV is not done.

Hepatitis E

The hepatitis E virus (HEV) is an RNA virus that is endemic in Southeast and Central Asia, Japan, the Middle East, North and West Africa, and Brazil and causes epidemics associated with fecally contaminated water. Sporadic infections occur in other developed countries. It usually causes a self-limited illness but can be lethal in pregnant women, their fetuses, and patients with chronic liver disease. Transfusion-related transmission was postulated on the basis of cohort studies in endemic countries that showed a high prevalence of anti-HEV among transfused patients. Blood transmission is rare but has been reported from endemic areas, and rarely in nonendemic regions, presumably resulting from an extended asymptomatic viremia. Transfusion-transmitted HEV has not been reported in the United States or most other developed countries, and screening is not under active consideration.

Non–A-E Hepatitis

Cases of posttransfusion hepatitis are still seen occasionally despite donor screening and recipient diagnostic testing for known hepatitis viruses, causing speculation that undiscovered hepatitis agents exist. Likewise, a small but consistent percentage of community-acquired hepatitis cases test negative for known hepatitis viruses, some cirrhosis is classified as "cryptogenic," an etiologic agent for hepatitis-associated aplastic anemia eludes description, and the cause of some cases of acute liver failure remains elusive. Several candidate agents have been proposed as non–A-E hepatitis viruses.

GBV-C (initially called hepatitis G virus [HGV]) is a flavivirus with no confirmed disease association that is transmitted parenterally, including frequently from transfusion. Of interest, GBV-C infection may delay progression of disease in those coinfected with HIV, which has led to studies of the interactions of these viruses.[4]

From 1% to 4% of U.S. blood donors are viremic compared with 15% to 20% of injection drug users who have detectable GBV-C RNA. Infection occurs frequently among those infected with HCV and HIV. More people have antibodies against the E2 envelope protein, in the absence of RNA, suggesting viral clearance. GBV-C has not been shown to cause liver disease or other morbidity, and hence there is no consideration of donor screening at this time.

The torque teno virus (TTV) complex is a genetically diverse group of nonenveloped DNA viruses in the family Circoviridae, which was discovered in 1997. They cause viremia, and they are transmitted by transfusion, but they cause no recognized liver disease or other clinical illness. Initial studies indicated a prevalence of viremia of 1% to 2% in North American blood donors, but recent studies targeting more diverse TTV variants have identified viremia in the majority of healthy donors, suggesting these agents are commensal and nonpathogenic. SEN virus (SENV), another member of the Circoviridae, was described using degenerate polymerase chain reaction (PCR) primers while working with TTV. After an initial report associating SENV variants in two patients with transfusion-associated non–A-E hepatitis, subsequent epidemiologic studies have failed to link SENV with clinical hepatitis. Thus GBV-C, TTV, and SENV do not represent clinically relevant hepatitis viruses, but it is anticipated that identification of new putative viral hepatitis agents will continue; the role and possible relationship of such agents to presumed non–A-E posttransfusion hepatitis awaits their discovery and analysis.

RETROVIRAL INFECTION

Human Immunodeficiency Virus

The human immunodeficiency viruses type 1 and type 2 (HIV-1 and HIV-2), pathogenic retroviruses of the family Retroviridae, genus Lentivirus, are the etiologic agents of the acquired immunodeficiency syndrome (AIDS). Molecular characterization divides HIV-1 into three groups: group M (main), group O (outliers), and group N (non-M/O). Group M subtype B infections predominate in the United States; only 3% of HIV-positive blood donors have non-B strains. Very rare group O infections have been detected in the United States among patients who were born, lived, or had sexual contact in endemic regions of West and Central Africa. HIV-2 infected persons in the United States, in contrast to those with HIV-1, are infected after heterosexual transmission from West African emigrants or residents. HIV-2 is less likely to cause AIDS and represents less than 1% of HIV cases diagnosed annually in the United States

Tests used currently for screening blood donors detect infection with all of these viruses.[5] Testing for HIV-1 began in 1985, for

HIV-2 in 1991 to 1992 (although HIV-1 tests before that time detected most HIV-2 infections) and for HIV-1 group O in 2003 to 2009.

Both serologic testing and NAT are performed on every blood donation. Antibody testing, implemented in early 1985, becomes positive, on average, 21 days after infection. NAT detects HIV RNA at a minimum concentration of 5.5 copies per milliliter; donor RNA screening has been performed since 1999. As is done for HCV because of the rapid ramp-up of viremia, the exquisite sensitivity of NAT, operational and cost-containment considerations, donor-testing laboratories pool aliquots from several donations (minipools) rather than test individual donations as is done for serologic tests. RNA is detected 5.6 to 9.0 days following infection, thereby substantially closing the seronegative-window period between HIV exposure and virus detection. Rare genetic variants of HIV may escape NAT detection when nucleotide sequence changes affect NAT primer or probe binding sites, but the vast majority of the these infections will be detected serologically.

To interdict donations in the window period between exposure and test positivity, each blood donor is asked at each donation about exposure risks using questions developed in the early to mid-1980s, subsequent to the first reports of AIDS in hemophiliacs and transfusion recipients. These initial interventions targeted blood donations from homosexually active men and injection drug users, substantially reducing the transmission risk between 1983 and 1985. Four transfusion transmissions have been documented subsequent to NAT testing, three before 2002 and one in 2008.[6] Modeling suggests a residual risk for HIV transmission persists at approximately one transmission per 1.5 million to 2.1 million donations, because NAT cannot detect HIV infection during the immunosilent 9-day eclipse phase between infection and test reactivity and due to very rare processing and quarantine procedure errors. Fourth-generation tests, under development, that combine HIV antibody and HIV antigen testing detect almost 90% of infections detected by NAT. Their role in future testing algorithms is unclear at this time, but their greatest utility may be in resource-constrained settings where NAT is not feasible.

The continued permanent lifetime deferral in the United States (and other countries) of men who have had sex with men even once since 1977 may be inappropriate from a risk-benefit perspective in light of improvements in donor testing. These stringent policies are being relaxed in some countries (e.g., Australia and the United Kingdom).[7] Reluctance to revise this policy in North America in pursuit of a zero-risk blood supply arises from unwillingness to accept any course of action that results in even a de minimis increased risk for transmission (see box on Blood Safety Decision Making).

Human T-Lymphotropic Virus-1 and Virus-2

Human T-lymphotropic virus-1 (HTLV-1) and HTLV-2 are closely related deltaretroviruses with 60% to 70% sequence homology and shared tropism for T lymphocytes. In contrast to HIV, HTLV is rarely present in cell-free plasma and shows little active replication in infected humans. HTLV-1 is distributed worldwide, with endemic foci in southern Japan, the Caribbean, certain parts of South America, Africa, the Middle East, and Melanesia. HTLV-2I is endemic among Amerindians in both North and South America and African Pygmies. An epidemic of HTLV-2I infections has occurred over the past 40 to 50 years among intravenous drug users in the United States, Brazil, and Europe. Transmission of both HTLV-1 and HTLV-2 occurs by parenteral exposures, sexual contact, and by vertical transmission from mother to child during pregnancy and breastfeeding.

Diseases associated with HTLV-1 infection include adult T-cell leukemia/lymphoma (ATL), HTLV-associated myelopathy/tropical spastic paraparesis (HAM/TSP), lymphocytic pneumonitis, uveitis, polymyositis, and arthritis. HTLV-2 does not appear to cause hematologic malignancy but has been associated with HAM/TSP and linked to a higher rate of common infections such as acute bronchitis, pneumonia, and urinary tract infections, suggesting a subtle immunomodulatory effect of the virus.[11]

ATL occurs in only 1% to 5% of infected persons following a latent period of decades. The illness is characterized by malignant lymphocytosis and leukemia, lymphadenopathy, hepatomegaly, abnormal liver function test results, splenomegaly, skin lesions, bone lesions, and hypercalcemia. HAM/TSP occurs in approximately 2% of individuals infected with HTLV-1 and HTLV-2. Patients with transfusion-associated HAM/TSP develop neurologic symptoms rather more rapidly, at a median of 3.3 years after transfusion. This illness is characterized by slowly progressive chronic spastic paraparesis, lower limb weakness, urinary incontinence, impotence, sensory disturbances, low back pain, hyperreflexia, and impaired vibration sense.

Blood donor screening for HTLV-1 antibodies began in 1988, and a more sensitive combination HTLV-1/2 EIA that detects close to 100% of HTLV-2 infections was introduced in 1998. The prevalence of true positive HTLV markers decreased approximately 10-fold during the 1990s to 0.01% in 2001 and has remained at this level. The rate is threefold higher in female compared to male donors. Incident infections are rare in repeat donors, an observation that has led to one-time testing of donors in some European countries, but an incidence of three per million donor years of follow-up is felt by some to be too high for adoption of this strategy in the United States. Cell-free components such as plasma and cryoprecipitate do not transmit HTLV, and less than 30% of infected cellular components transmit. The residual risk for transfusion-associated HTLV infection using contemporary serologic testing is approximately 1 per 2.4 million donations. The contribution of blood-donor serologic testing to this low residual risk is confounded by the effect of effective leukoreduction that reduces HTLV-1 copy numbers in red blood cells (RBCs) by up to 6 logs, to below the infectious dose of 10^7 to 10^8 infected cells per unit (one of a number of arguments used in support of universal leukoreduction of blood components).

The deferral, notification, and counseling of healthy blood donors after a repeatedly reactive screening test for HTLVs is problematic, and tens of thousands have been affected since screening started. The vast majority of such tests are false positive, and there are no licensed confirmatory tests available for the HTLVs, leaving donor-testing laboratories to use unlicensed and largely unregulated supplemental tests to explicate reactive screening results. Recognizing this deficiency, the FDA approved an algorithm that accepts nonreactivity, on further testing of the original donation, using a second licensed donor-screening test from a different manufacturer as evidence that infection is absent. Alternatively, if the second screening with an alternate test is not done, donors may continue to donate as long as subsequent donations are negative on the original screening test. This complex algorithm resolves many false-positive screening results, but there remain a large number of notifications for false-positive reactivity, and it does not address the issue of the most appropriate counseling messages for false-positive donors. This frequently results in a mixed message to donors that they are uninfected based on available test results, but that they are nevertheless deferred from future blood donation.

HUMAN HERPESVIRUS INFECTIONS

Human herpesviruses (HHVs) are enveloped, structurally complex double-stranded DNA viruses that cause common infectious diseases. Primary infection is followed by lifelong carrier states and the possibility of reactivation. They are classified in three subfamilies, Alphaherpesvirinae, Betaherpesvirinae, and Gammaherpesvirinae, of which the latter two contain the herpesviruses that are of greatest concern from a transfusion medicine standpoint. Members of the Alphaherpesvirinae subfamily, herpes simplex viruses (HSVs) and varicella-zoster virus (VZV), rarely if ever cause transfusion-transmitted infections. Transfusion-transmitted cytomegalovirus is well recognized. Transmissions of EBV, HHV-6, HHV-7, and HHV-8 by blood appear to be rare or nonexistent in the United States.

Blood Safety Decision Making

Most consider the blood supply in the developed world to be at its highest historical safety level. This reflects incremental improvements in donor selection and history screening, blood testing, and process control that span four decades. For years, blood collection professionals and government regulators formulated blood safety policy decisions on the premise that a zero-risk blood supply was achievable. In part, this reflects the perceived tardy transfusion medicine community's response in the early 1980s to the emergence of human immunodeficiency virus (HIV) in the blood supply and the recognition (of) the scope and severity of posttransfusion non-A, non-B hepatitis (subsequently hepatitis C [HCV]) following that. It reflects also the "dread fear" associated with transfusion-associated HIV. This visceral reaction occurs when devastating, unpredictable, and stigmatizing events threaten potential victims who have minimal avoidance discretion. This fear was validated by numerous transfusion-related HIV cases. It was amplified by widely publicized lawsuits, indictments, and criminal convictions of health ministers and policy makers in the 1980s and 1990s (*l' affaire du sang contaminé* in France addressing HIV and Canada's Royal Commission of Inquiry on the Blood System into blood collection agencies' response to non-A, non-B hepatitis risk).

Not surprisingly, from the 1980s until now, donor deferrals and blood-testing interventions have been rapidly, successively, and additively implemented for emerging and theoretical risks. Collection facilities introduced anti-HBc and alanine aminotransferase (ALT) testing as surrogates for non-A, non-B hepatitis, HIV p24 antigen testing, then nucleic acid testing (NAT) for hepatitis C, HIV, extensive deferrals for the risks attending transmissible spongiform encephalopathies (TSEs,) NAT for West Nile virus (WNV) and hepatitis B, and antibody testing for *Trypanosoma cruzi.* The cost-benefit estimates for some of these interventions exceeded by orders of magnitude generally accepted thresholds but did not deter their adoption. For example, the costs per quality-adjusted life-year proximate to implementation include HIV NAT, $1,966,000; HCV NAT, $1,830,000; WNV NAT, $520,000 to $897,000; human T-lymphotropic virus (HTLV) antibody testing, $63,000,000; and *T. cruzi* antibody testing, $2,123,000 (Fig. 121-1). It is unlikely that this reactive approach can be sustained in the current health care–reform environment.

Application, after HIV entered the blood supply, of a stringent form of the precautionary principle (originally promulgated for environmental protection, not transfusion safety) pushed decision making toward avoidance of all risks. The precautionary principle promotes implementation of measures to mitigate risk even if evidence of a risk is incomplete. It is supposed to be tempered by proportionality; that is, any measures adopted are to be proportional to the risk and with those used in similar circumstances, but some have argued that this has not been the case with blood safety measures, at least by the metric of cost-benefit. Nevertheless, although in potential conflict with evidence-based decision making, this approach resonated with policy advocates charged with transfusion safety. The impact on transfusion safety is mixed. In retrospect, the implementation of HIV p24 antigen testing in the mid-1990s despite enormous studies demonstrating its lack of utility was extreme. Likewise, the recent decision to defer donors with chronic fatigue syndrome, based on a single study, to prevent xenotropic murine leukemia virus–related virus (XMRV) transmission was not necessary. Continued lifetime deferral of men having sex with men even once since 1977 is seen by many to be discriminatory in light of increasingly sensitive in vitro tests and alternative approaches to other risk behaviors. In contrast, when the risk for transfusion transmission of vCJD was theoretical, modeling was used to balance any such danger against the impact of broad donor deferrals on the adequacy of the blood supply and to arrive at a policy decision. Some argue that the magnitude of risk does not justify the stringency of donor criteria and number of resulting deferrals given the tiny risk in a country that is not bovine spongiform encephalopathy (BSE) endemic, but the process was rational and should perhaps be seen as a precedent that "an acceptable risk" is estimable.

Hemovigilance programs, such as the Serious Hazards of Transfusion (SHOT) in the United Kingdom and others in Canada, France, and a fledgling program in the United States, have emerged, supplying evidence about a much broader range of transfusion hazards than just infections. For example, a data-driven decision to minimize plasma transfusions from potentially alloimmunized female donors resulted in a dramatic reduction in transfusion-related acute lung injury in the United Kingdom, and early studies in the United States are consistent with this effect.

These systems provide an opportunity for monitoring the risks and benefits of new initiatives, (e.g., proactive pathogen reduction). Pathogen-reduction processes (see box on Pathogen Reduction) offer the opportunity to abrogate most of the residual risk for all of the historically important transfusion-transmitted infections, bacterial contamination, babesiosis, malaria, WNV, and Chagas disease. Pathogen reduction could eliminate the often lengthy, reactive, iterative paradigm of emergence of a new pathogen in the population, recognition of a material threat to transfusion recipients, development of donor-deferral strategies followed by development and refinement of test systems that has characterized our historical approach. Critically, broadly active pathogen-reduction processes offer a layer of protection against unsuspected emergence of new agents. If already in use, they would need only to be validated as active against a new agent or appropriate model agents. The challenge to precautionism is balancing the impact of pathogen reduction on product quality and the potential long-term toxicities that may not be apparent in premarketing clinical trials against the unquantified probability that new agents will emerge and threaten enough morbidity to make pathogen reduction clinically and economically feasible.[8]

More recently, as cost pressures for health care increase, transfusion professionals are questioning whether the zero-risk paradigm remains relevant. A consensus conference held in Toronto in October 2010 addressed concerns about "safety at any cost" and inconsistent decision-making practices affecting the blood supply.

The conference's consensus statement potentially portends a paradigm change toward risk-based decision making: risk identification, risk assessment, risk management, and risk communication.[9] Risk will never be zero, and there is now a realization that cost considerations,[10] politics, ideology, and public opinion cannot be ignored. Further policy making considerations will likely take these factors into account, balancing risk, safety, stakeholder interest, and overall impact on public health.

Cytomegalovirus

Cytomegalovirus (CMV), a betaherpesvirus, infects a wide range of cell types, including leukocytes of the monocyte-macrophage lineage and their progenitors. The former represents the preeminent source of transfusion-transmitted infection. Consequently, acellular blood components (plasma, cryoprecipitate) do not transmit CMV, and effectively leukocyte-depleted cellular components do so rarely.

Primary CMV infection in immunocompetent individuals is usually community acquired, often asymptomatic or associated with a mild, self-limited infectious mononucleosis syndrome. After virtually all infections, latent virus persists permanently in cellular reservoirs, allowing lifelong reactivation, and in the setting of transfusion or transplantation, the potential for viral transmission via unmanipulated cellular blood products, and allografts.

In immunosuppressed patients, CMV infection can cause severe morbidity and mortality from pneumonitis, hepatitis, gastroenteritis,

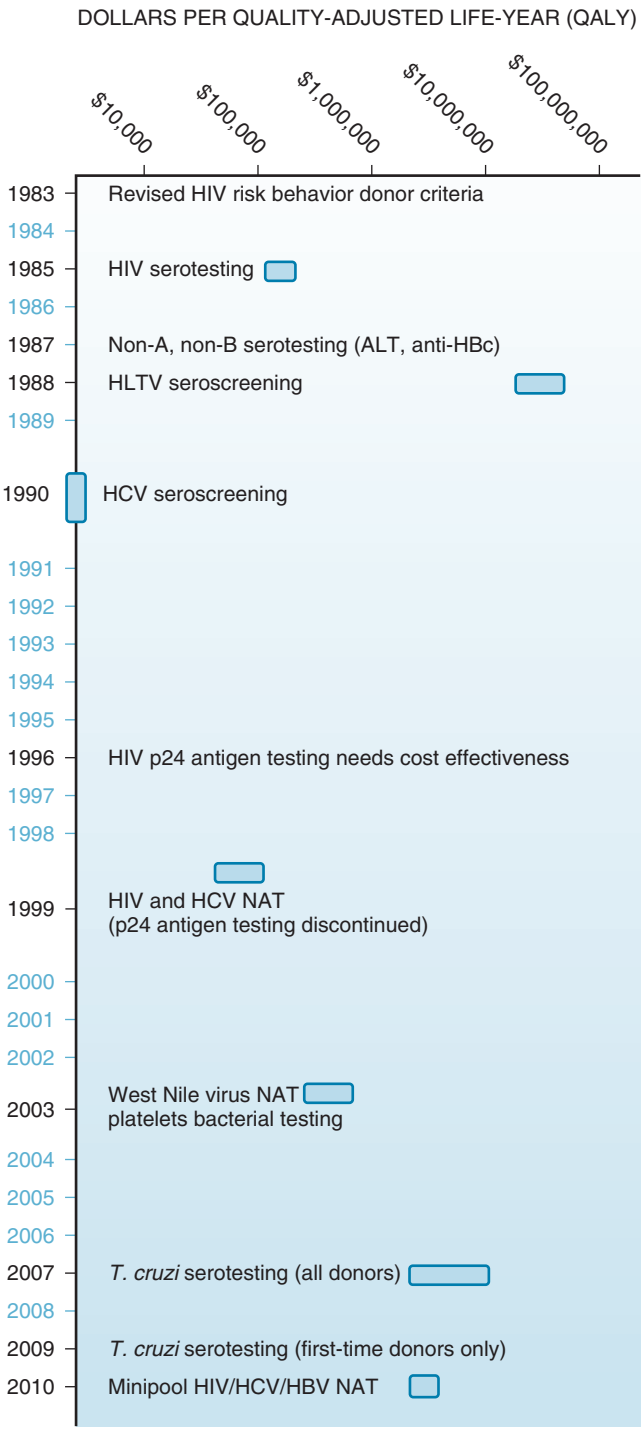

Figure 121-1 VARIOUS SAFETY MEASURES INTRODUCED DURING THE PAST THREE DECADES ENHANCED TRANSFUSION SAFETY. The x-axis displays costs associated with these advances per quality-adjusted life-year (QALY). Hepatitis C virus (HCV) seroscreening saves costs. Estimates for platelet bacterial culturing and human immunodeficiency virus (HIV) p24 antigen testing are not available. *ALT,* Alanine aminotransferase; *anti-HBc,* antibodies against HBcAg; *HBV,* hepatitis B virus; *HLTV,* human T-lymphotropic virus; *NAT,* nucleic acid testing; *T. cruzi, Trypanosoma cruzi.*

retinitis, and other inflammatory conditions. CMV infection in low-birth-weight infants is associated with sepsis-like syndromes, respiratory distress, and liver and bone marrow dysfunction. Their infections can be acquired in utero, from breast milk, or from transfusion. Reported infant morbidity varies considerably but can approach 50%

Table 121-2 Patients Benefiting From Cytomegalovirus Risk–Reduced Blood Components*

Infants <1200 g with CMV-seronegative mothers
Seronegative autologous and allogeneic (CMV-seronegative donors) stem cell transplant recipients
Seronegative stem cell transplant candidates
Seronegative recipients of seronegative solid organ transplants
Seronegative pregnant women
Fetuses receiving intrauterine transfusions
Immunosuppressed patients receiving granulocyte transfusions
HIV-seropositive/CMV-seronegative patients

CMV, Cytomegalovirus; *HIV,* human immunodeficiency virus.
*CMV risk–reduced components include CMV-seronegative and leukocyte-reduced components.

of seronegative low-birth-weight infants receiving unscreened, non-leukoreduced blood. CMV-seronegative marrow transplant patients are also susceptible to CMV infection, with approximately 30% of those infected developing symptomatic CMV disease before the adoption of routine monitoring for CMV antigen or nucleic acid in transplant recipients with provision of preemptive antiviral therapy. Seronegative solid organ transplant recipients are also susceptible to symptomatic transfusion-transmitted CMV infections. CMV-seronegative HIV-infected patients, although fewer in number, are another group at risk for transfusion-transmitted primary CMV infection. The reported risk for (usually asymptomatic) CMV infection in seronegative immunocompetent patients who receive non–leukocyte reduced cellular blood components unscreened for presence of CMV antibodies is approximately 1%. In contrast, the historical risk for CMV infection in immunosuppressed recipients receiving CMV-unscreened, non–leukocyte reduced blood components varies from 13.5% to 53.3%.

In the United States, in the population-based National Health and Nutrition Examination Survey (NHANES) III study, 58.9% of individuals more than 5 years old were seropositive, indicating prior CMV infection. The prevalence is age dependent, rising to over 90% in octogenarians, and is also dependent on race/ethnicity and other demographic indices. Such high seroprevalence rates mean that timely provision of components from seronegative donors from some donor populations can be challenging.

Selection of CMV seronegative and/or leukocyte-reduced blood components for susceptible patient groups has markedly reduced the risk for transfusion-transmitted CMV infection. Neither method is fail-safe in preventing transfusion-associated CMV transmission, however, and the place of one or both methods to supply "CMV-safe" blood components is an open controversy. In a metaanalysis of 11 controlled trials in allogeneic marrow transplantation 12 of 829 recipients of seronegative units versus 24 of 878 receiving leukoreduced but unscreened units developed CMV infections.[12] Pooling of data from three studies of seronegative or leukocyte reduced components, in comparison with CMV unscreened components, demonstrated statistically identical 93.1% and 92.3% reduced risks of CMV infection, respectively. Clinical outcomes would not be expected to be different in the setting of CMV antigen or DNA monitoring and preemptive antiviral therapy, but this has not been demonstrated in a rigorous study.

Current practice in the United States is diverse. Sixty-five percent of respondents to a recent survey considered leukoreduction and serologic screening to be equivalent, but practices for individual patient populations were divergent. In particular, clinicians caring for neonates were more likely to require serologic screening. In the absence of clear-cut scientific data and interpretation, the American Association of Blood Banks (AABB) recommends that each institution review its internal policies for blood use in patients vulnerable to CMV infection. Table 121-2 lists patient populations for whom use of "CMV risk–reduced" components, that is, CMV seronegative,

leukocyte reduced, or both, are thought to be beneficial. The failure of clinicians to recognize recipients requiring CMV-safe transfusion and to request such components is an argument that has been advanced in support of universal leukoreduction. If leukocyte reduction is chosen as a means to reduce the risk for CMV transmission, components prepared by prestorage leukocyte reduction should be selected because leukocyte removal by this method is more reliable than bedside filtration, probably related to much more stringent process controls in blood collection facilities.

NAT on blood donors for CMV genomic sequences in plasma is discussed as an approach for additional risk reduction, because rare blood donors present with window-period infections before emergence of CMV antibody and their donations might be detected for diversion from at-risk recipients. Current NAT assays do not seem to be more effective than serologic screening in detecting latently infected healthy blood donors, because CMV DNA was not reproducibly detected in a cohort of 514 unequivocally seronegative samples. Any consideration of additional testing is complicated by the absence of randomized studies using contemporary leukoreduction methods and by our lack of understanding of the clinical impact of transfusion-transmitted CMV in an era of CMV monitoring and treatment.

EPSTEIN-BARR VIRUS (HHV-4)

Epstein-Barr virus (EBV), a gammaherpesvirus, is the causative agent of heterophile antibody-positive infectious mononucleosis and is etiologically associated with Burkitt lymphoma, nasopharyngeal carcinoma, and posttransplant lymphoproliferative disease. Transfusion transmission of the virus is unusual because more than 90% of the adult population is infected, and second infection is prevented by host virus-specific cytotoxic T lymphocytes, capable of lysing EBV-infected B lymphocytes when viral peptides are expressed on the lymphocyte surface. Rare cases of transfusion-transmitted EBV presenting as infectious mononucleosis have been described in immunocompetent recipients and in immunosuppressed patients following solid organ transplantation. Aggressive EBV-associated lymphoproliferative disorders have been observed in patients with immune injury after cord blood stem cell transplantation but have not been documented following transfusion. B lymphocytes are the likely source of transfusion-transmitted EBV infection, so leukoreduction is an attractive strategy to prevent infection in transfusion recipients. Nonclinical studies suggest that leukoreduction is capable of removing detectable EBV DNA from platelet concentrates and RBCs.

Kaposi Sarcoma Herpesvirus (HHV-8)

HHV-8 is a gammaherpesvirus causally linked to Kaposi sarcoma, primary effusion lymphoma, and multicentric Castleman disease. It is highly cell-associated with lymphocytes and monocyte-macrophages. Although generally spread person to person, including sexually, it has been shown to be transmitted by transplantation. There is convincing evidence of HHV-8 transmission by transfusion in sub-Saharan Africa, where the seroprevalence of HHV-8 among blood donors is 40%, and fresh, nonleukoreduced blood transfusions are commonly used. The seroprevalence of HHV-8 among U.S. blood donors has been reported to be as high as 20% to 25%, but a multicenter study using well-characterized antibody tests on donations from five representative U.S. regions estimated a seroprevalence of only 3.5% and showed no evidence of viremia by PCR. The possibility has been raised that transfusions in the United States have transmitted HHV-8, but subsequently reported studies comparing transfused patients with untransfused controls are not suggestive. Similar to what has been established for CMV infection, it is assumed that widespread leukocyte reduction in the United States mitigates the risk for HHV-8 transmission by transfusion, but this has not been proven in a rigorous trial.

Other Herpesviruses (Herpes Simplex, Varicella-Zoster Virus, Human Herpesviruses 6 and 7)

Infection with these viruses is very common to ubiquitous. Fifty percent to 80% of the adult population is seroreactive to HSV-1 and/or HSV-2, up to 95% for VZV, more than 90% for HHV-6, and 70% to 90% for HHV-7. Primary infection is followed by lifelong latency for all human herpesviruses, and reactivation from latency is described for all. There is no credible evidence of transfusion transmission of HSVs (causing orolabial and genital herpes and herpes encephalitis), VZV (chickenpox and shingles), or HHV-6 or HHV-7 (exanthem subitum or roseola infantum, multiorgan dissemination with reactivation in immunocompromised hosts).

Viremia occurs during both primary and reactivation infection with HSV and VZV, but transmission by blood has never been alleged for these viruses. Although the lymphocyte association of HHV-6 and HHV-7, like CMV and EBV, suggests the possibility of transfusion transmission, well-documented case reports or series are not available. Case reports of HHV-6 transmission by hematopoietic stem cells used molecular methods to detect integrated donor HHV-6 DNA in engrafted donor cells and appear to represent transmission of latently infected cells rather than of active infection. Furthermore, transplant recipients may reactivate preexisting latent infection, thereby confounding the evaluation of potential transfusion transmission. HHV-6 and HHV-7 are highly leukocyte associated after primary infection, and leukoreduction would be expected to be effective by analogy to human CMV; however, cell-free viremia can be found during primary infection.

PARVOVIRUS

Human parvovirus B19 (erythrovirus) is a 19- to 23-nm-diameter nonenveloped, single-stranded DNA virus from the family Parvoviridae, as are adeno-associated viruses, human parvovirus 4 (PARV4), PARV5, and bocavirus. B19 has at least three genotypes. Genotype 1 infections appear predominantly in the United States and Europe. Genotype 2 infections appear confined to those born before 1973, and genotypes 3a and 3b infections occur in parts of West Africa. Infection with B19 is ubiquitous, with 50% of high school children demonstrating seropositivity, increasing to 90% in older adults. Approximately three-quarters of transfusion recipients have B19 IgG antibodies. Natural transmission occurs through the respiratory route most commonly and transplacentally to the fetus in up to 30% of women infected during pregnancy. Transfusion of blood and blood components, plasma derivatives, and organ transplantation are minor routes. In women infected during weeks 9 to 20 of pregnancy, fetal death occurs in 10% to 15% from hydrops fetalis. The low observed incidence of infection in transfusion recipients results from prior infection and immunity, coinfusion of neutralizing antibodies, and/or because of low viral loads in components from healthy donors (less than 10^5 to 10^6 International Units per milliliter).

Parvovirus B19 causes erythema infectiosum, or fifth disease, oligoarthritis, and neurologic and myocardial infections. Following acute infection, viral replication leads to extremely high-titer viremia that declines at the time of IgM seroconversion approximately 9 days following infection. B19 may persist in bone marrow, liver, tonsils, and skin of healthy persons with no recognized clinical significance, and low levels of B19 DNA have been amplified from the blood of healthy people for several years after primary infection. The virus is highly tropic for erythroid progenitor cells using the P blood group antigen, or globoside, as its receptor, causing aplastic crises in patients with sickle cell anemia, other inherited hemolytic diseases, and conditions associated with decreased RBC survival, malaria, and HIV/AIDS. Acute infection impairs erythropoiesis for 7 to 10 days, with complete cessation for 3 to 7 days, resulting in hemoglobin decreases. Persistent infection, causing red cell aplasia, occurs in those who fail to develop neutralizing antibodies to the viral capsid protein 1. In these patients, the virus continues to circulate at high titer, greater

than 10^{12} genome copies per milliliter. Patients at risk for persistent infection include those receiving intense chemotherapy and immunosuppression, organ transplant recipients, and those with HIV. Infection in these groups tends to respond favorably to intravenous immunoglobulin infusions.

B19 virus–impaired erythropoiesis appears to be multifactorial. B19 virus nonstructural protein 1 (NS1) mediates apoptosis; an 11-kDa protein perturbs signal transduction and induces apoptosis. B19 virus DNA activates Toll-like receptor 9 inhibiting cell growth and is toxic for infected cells.

Blood and plasma-derivative transmission involves donations during the transient 1- to 2-week high-titer viremic period. The prevalence of B19 viremia has been reported as 0.003% to 0.84% in blood and plasma donors. In one study, 43% of blood donations had low-titer viremia (less than 10^3 International Units/mL). In a study involving more than 12,100 B19 DNA–tested blood donations, given to surgical patients with a 78% pretransfusion B19 IgG seroprevalence, no B19 transmissions occurred from transfusions containing less than 10^6 International Units/mL. Hence most blood transfusion recipients are at low risk for an infectious exposure.[13]

By contrast, recipients of plasma-derived products made from manufacturing pools of thousands of donations have a significant risk because the virus survives partitioning, ethanol fractionation, and other antiinfective measures applied to derivatives, and a single high-titer viremic donation can overcome the neutralizing activity of antibody in the pool. Recipients of coagulation concentrates are at highest risk, whereas those of intravenous immunoglobulin and albumin are less so in cohort studies of prevalence. In one report 14% of viremic plasma donors had titers between 10^4 and 10^7 genome equivalents per milliliter, and one in 13,000 had titers greater than 10^7. In observational studies, seroconversion occurred among recipients of plasma derivatives with high titers, $10^{7.5}$ to $10^{8.5}$ International Units/mL, treated with the solvent/detergent pathogen-reduction technique, suggesting that the protective effect of neutralizing anti-B19 antibodies is exceeded in the presence of high viral loads (see box on Pathogen Reduction). Solvent/detergent pathogen-reduction treatment is ineffective in preventing B19 transmission in hemophilia patients receiving factor concentrates. Freeze-drying and dry-heat treatment (80° C [176° F] for 72 hours) inactivate more than 4.7 logs B19, but this is not always sufficient to prevent transmission. Fortunately, clinical morbidity from plasma derivative infections is minimal. Of note, PARV4 and PARV5 have been detected in pooled plasma derivative samples, but the clinical significance is not known.

Currently, plasma derivative manufacturers use "in-process" NAT to identify and remove source (paid donor) and recovered (untransfused plasma from volunteer whole-blood donations) plasma units with parvovirus B19 DNA titers greater than 10^4 International Units/mL. Approximately 1 per 10,000 plasma units is withheld from further processing. For volunteer whole-blood donors, 1 per 6,000 to 1 per 16,000 have titers greater than 10^6 International Units/mL. Because individual whole-blood donations rarely cause recognized parvovirus infection, testing of single red cell units, platelets, or plasma for transfusion for B19 DNA is not currently required, although some advocate use of B19-tested blood components for those potentially at risk, including pregnant women, neonates, those with reduced RBC survival, and immunocompromised patients.

WEST NILE VIRUS

West Nile virus (WNV) is a mosquito-borne lipid-enveloped RNA virus in the Japanese encephalitis complex of the Flaviviridae. Transmitted bird-to-bird primarily by culicine mosquito vectors, human infections occur incidentally. The first cases were identified in the West Nile district of Uganda in 1937. Subsequently outbreaks occurred in the Middle East, South Africa, and Europe. The first North American cases appeared in New York City in 1999. Starting in July 2000, WNV cases spread to the Mid-Atlantic states. This was followed in the next 3 years by transcontinental dissemination. During the summer of 2002, a model suggesting a significant risk for WNV infection in blood donors was published,[16] and then four recipients of organ allografts from a single donor developed neuroinvasive WNV infection. Infection of the organ donor was traced to donor blood transfused before death from trauma. The model and this case provoked a multidisciplinary effort, successfully engaging the blood community, the manufacturers of blood donor–screening NAT platforms, and public health officials and regulators to develop and deploy, under an investigational new drug (IND) exemption, high-throughput screening tests in the 10 months before the 2003 transmission season began. WNV test implementation represents the benchmark for responsiveness to a serious emerging transfusion-transmitted infection in the United States.

In 2003, 9862 clinical WNV cases were reported and more than 1000 healthy blood donors tested positive. In 2004, case reports declined in the Northeast but extended westward into Arizona and Southern California. In 2005, more than 2800 clinical cases were reported, with approximately 25% occurring in California, relatively high activity in South Dakota, Nebraska, Louisiana, and Illinois, and low activity in the Northeast. In 2006, approximately 400 viremic blood donors were identified, and more than 4050 cases occurred. Subsequently WNV activity was reported in Washington state for the first time, and high rates of infection were noted in Idaho, California, Nebraska, Illinois, Louisiana, and the Dakotas; more than 340 blood donors had positive test results. By 2010, fewer than 150 blood donors tested positive with the highest frequencies in New York, Texas, Arizona, and California.

WNV viremia appears 1 to 3 days after a bite of an infected mosquito. In contrast to HIV and HCV, peak WNV levels are low (median 3500 copies/mL compared to 10^5 to 10^7 copies for HIV and HCV). In cohort studies of blood donors with positive WNV RNA tests, only 29% to 61% (retrospectively) describe any symptoms before or after donation consistent with WNV infection, compared to 3% to 20% of those not infected, demonstrating that the donor history is neither sensitive nor specific enough to prevent transfusion transmission.[17] Testing for antibodies also will not prevent transmission because IgM antibodies appear a median of 14 days and IgG antibodies a median of 17 days after infection and infectivity disappears rapidly with the development of antibody. These data explain the selection of WNV NAT for the testing strategy. To maximize efficiency, donors' samples were tested in minipools containing aliquots from 6 to 16 donors, as is done for HCV, HBV, and HIV.

Despite minipool NAT, six transfusion-associated WNV cases occurred during 2003. The implicated donors had low-level antibody-negative viremia that escaped detection in the minipool (i.e., diluted) samples. Subsequently test performance has improved, and, more critically, blood collection organizations have developed strategies to switch to NAT on individual donation aliquots in areas experiencing high WNV activity. One transfusion-associated case occurred in 2004 and one in 2006. Of the 30 cases reported before 2006, all implicated donations tested WNV IgM-antibody negative. The last reported transmission was in 2008 when a blood donor was missed from a collection facility using less-stringent regional WNV activity criteria for triggering a conversion to individual donation testing.

DENGUE VIRUSES

This mosquito-borne infection is of great interest as an emerging pathogen with the potential to spread by transfusion. Forty percent of the world's population live in areas with risk for dengue, including many areas visited by U.S. travelers. It has spread rapidly in Latin America and the Caribbean since the 1980s. Dengue is endemic in Puerto Rico, the U.S. Virgin Islands, and American Samoa, and there have been outbreaks in Hawaii, Texas, and Florida during the last 10 years. Dengue is caused by four related flaviviruses spread person to person by *Aedes aegypti* and *Aedes albopictus,* which are present in 16 and 35 states, respectively, in the United States.

Most infections are asymptomatic, but illness ranges from undifferentiated fever to classic break bone fever and severe dengue (dengue hemorrhagic fever and dengue shock syndrome). An approximately

Pathogen Reduction

Our approach to new transfusion-transmitted infections is intrinsically reactive. We await disease emergence and identification of the new agent, develop an understanding of the infection's risk factors, devise donor deferrals, and then implement screening assays. Before deploying a sensitive and specific test, morbidity and mortality will accumulate. This reactive strategy will continue unless more broad-reaching interventions are brought forward. Pathogen-reduction technology (PRT) offers a proactive strategy to address new threats; these technologies involve physical, chemical, and photochemical treatments of blood components to inactivate or decrease viral, bacterial, and parasite infectivity.[14]

Beginning in the 1980s, heat treatment, nanofiltration, and solvent/detergent treatment eliminated or reduced viral transmission in products derived from large-scale plasma fractionation such as albumin, immunoglobulin, and hemostatic factor concentrates.

In the past decade, attention turned to whole blood–derived components: frozen plasma, platelets, and red cells. For these, PRT utilizes methylene blue and visible light treatment for plasma; amotosalen (psoralen) and ultraviolet A (UVA) light, and riboflavin (vitamin B_2) and UVB and UVA light for plasma and platelets; and riboflavin/UV light and S303 (a labile alkylating compound) for red cells. Many European countries use PRT for platelets and plasma. None is implemented in North America at this time.

Amotosalen/UVA and riboflavin/UV have advanced furthest in investigation in North America. They provide significant antiviral activity against all agents for which tests are performed currently, human immunodeficiency virus (HIV), hepatitis B and C, human T-lymphotropic virus (HTLV), West Nile virus, *Trypanosoma cruzi,* and cytomegalovirus. PRT also inactivates agents causing bacterial contamination of platelets; inactivates white blood cells to prevent transfusion-associated graft-versus-host disease; decreases formation and release of cytokines during storage, reducing febrile, nonhemolytic transfusion reactions; and abrogates white blood cell–induced alloantibody (e.g., human leukocyte antigen (HLA) antibody) formation mitigating alloimmune platelet refractoriness.

Adverse events linked to PRT relate to toxicity and cost. Toxicity affects cell function and recipient safety. Solvent/detergent-treated frozen plasma products prepared commercially in pools of 500 to 2500 donations distributed in the 1990s had reduced α_2-antiplasmin, antitrypsin, and protein S levels. They were associated with deep venous thrombosis in patients with liver disease and, in 2002, withdrawn by the manufacturer. A reformulated product used in Europe has not been associated with these events but has not been submitted for regulatory approval in the United States. Solvent/detergent is not active against hepatitis A or parvovirus. Because solvent/detergent disrupts lipid membranes, it cannot be used with cellular components.

Methylene blue and visible light inactivates pathogens in plasma by targeting nucleic acids. However, it alters fibrinogen structure. Because it damages cell membranes, methylene blue is not used for platelets or red cells. It is not effective against hepatitis A or parvovirus and is not recommend for treatment of thrombotic thrombocytopenic purpura.

Amotosalen/UVA and riboflavin/UVB also target nucleic acids. Treated plasma retains 72% to 77% of fibrinogen and factor VIII levels, greater than 80% of protein S and α_2-antiplasmin, and 96% of ADAMTS13 (a disintegrin and metalloproteinase with thrombospondin motifs 13). Platelets treated with these technologies have approximately 30% lower 1-hour posttransfusion corrected-count–increments than control platelets.[15] In clinical trials, mild and moderate bleeding frequency is increased, but not severe bleeding complications; and the time between transfusions and total platelet transfusions has not generally been different. It is unclear whether a proportion of platelets is impaired (in which case, platelet dose escalation would ameliorate concerns about lower corrected count increment) or all platelets are affected (increasing the dose would be insufficient). Pulmonary toxicity similar to transfusion-related acute lung injury (TRALI) has been reported in clinical trials and in animal model experiments in which UV light has been implicated. Previous clinical trials in red blood cells (RBCs) were halted because of nonsymptomatic immunoreactivity against S303–induced red cell neoantigens and are being resumed with a reformulated process. Preliminary reports suggest riboflavin/UV causes functional impairment in red cells stored nearest the 42-day expiration date.

Toxicity relates also to residual chemical contamination. However, amotosalen and its products are removed before infusion, and chemical removal is unnecessary for riboflavin-treated blood components.

Cost-effectiveness studies project $1.3 million per quality-adjusted life-year (QALY) for PRT whole blood and $1.4 million per QALY for PRT platelets and plasma. This is costly, but consistent with NAT for HIV, and these analyses do not integrate the risk- or cost-benefit of mitigating an unanticipated emerging pathogen.

The toxicity issues likely will be resolved through technical adjustments. Cost, presumably, would decrease following large-scale implementation.

Interest in PRT remains high because it reduces sepsis-related platelet transfusion complications; inactivates parasites such as *Babesia microti,* and *Plasmodium falciparum;* mitigates risks associated with recognized emerging pathogens such as dengue and chikungunya viruses; and proactively decreases threats from unknown, emerging pathogens.

7-day viremia is a feature of both asymptomatic and symptomatic infection, and asymptomatic blood donors from Hong Kong, Singapore, and Puerto Rico have transmitted dengue to blood recipients. Although such reports are limited, compared to the high rates of vector-borne infection, there is no systematic surveillance for transfusion-transmitted dengue and its recognition in the face of widespread outbreaks is problematic.[18] Viremic, well donors have been identified in Brazil, Central America, and Puerto Rico using NAT and antigen detection tests. Rates of donor viremia in Puerto Rico are comparable to those found in U.S. donors during the most active WNV seasons.

The current risk for dengue from transfusion in the United States relates mainly to return of infected, asymptomatic or presymptomatic travelers to the United States from endemic areas (blood products imported to the mainland from Puerto Rico during dengue activity are screened). A 3- to 14-day incubation period precedes symptom onset. Deferral for travel to malarious areas (1 year for a U.S. native) offers some protection, but a large proportion of dengue-affected areas frequently visited from the United States are malaria-free and donor-travelers to those areas can introduce the virus into the community and the blood supply. Careful surveillance and a high index of suspicion when sustained febrile illness occurs following transfusion are required to recognize transfusion dengue. Preliminary data on travelers from the United States to dengue-endemic destinations that are malaria-free suggest that 2- to 4-week deferral for travel to dengue-affected areas may have a greater adverse impact on blood donation than current malaria deferrals. The conditions for sustained spread of dengue exist in large areas of the United States: a source of infection from travelers and immigrants; a susceptible population; and competent vectors. Whether the recently identified outbreaks in the United States will continue or increase, and whether sustained transmission will begin is unknown. Transfusion-transmitted dengue has been identified by one group as one of the three highest-priority emerging infections posing a potential threat to transfusion recipients

Emerging Infections

The experiences with human immunodeficiency virus (HIV), new variant Creutzfeldt-Jakob disease (vCJD), and West Nile virus (WNV) have made it clear that planning for the emergence of new pathogens that may threaten the blood supply is critical in order to shorten the interval from emergence to mitigation. To that end, the characteristics of pathogens likely to enter the blood supply must be understood. These include the ability of the agent to establish an asymptomatic blood-borne phase, to survive under contemporary processing and storage conditions, to establish infection by the intravenous route, and to cause significant morbidity in a transfusion recipient.

Using these characteristics and a review of contemporary literature, the Transfusion Transmitted Diseases Committee of the American Association of Blood Banks (AABB), from 2005 to 2009 produced a compendium of infectious agents that might become relevant to transfusion medicine and attempted to prioritize those that were identified.[19] A series of 68 fact sheets was developed. The fact sheets provide transfusion medicine professionals and clinicians with an overview of the agents' phylogeny, epidemiology, clinical characteristics, and interventions that might be useful to protect the safety of the blood supply. Three agents were included in the highest priority stratum: *Babesia* sp., dengue viruses, and the vCJD prion; a section on each is included in this chapter. The fact sheets are freely available online, cover many of the agents discussed in this chapter, and are to be updated when required.

Since the original publication, several new monographs have been added, reflecting an ongoing "horizon-scanning" initiative designed to alert the medical community to potential threats. These include yellow fever and the yellow fever vaccine viruses after the latter was transmitted to blood recipients when recent vaccine recipients failed to divulge that information during blood donation, and xenotropic murine leukemia virus–related virus after alleged associations with prostate cancer or chronic fatigue syndrome/myalgic encephalitis were published (see box on Xenotropic Murine Leukemia Virus–Related Virus). Other fact sheets have been updated and rereleased to capture relevant new information. The availability of these materials to the transfusion medicine and general medical communities is meant to increase awareness that unexpected infections in transfusion recipients should trigger consideration of that source and to provide background allowing the rational consideration of approaches to avert and minimize their spread.

in the United States and Canada and has been the subject of discussions at the FDA's Blood Products Advisory Committee (see box on Emerging Infections).

PANDEMIC INFLUENZA A

There was interest in the transfusion safety implications of influenza A even before the swine origin A-H1N1pandemic of 2009-2010.[22b] Viremia in donors, and the potential for infection of recipients were discussed during meetings of an AABB pandemic influenza planning task force as early as 2008, based on old literature demonstrating the virus in the blood of experimentally infected volunteers and case reports of viral dissemination during human infection with highly pathogenic avian A-H5N1 virus. Subsequent studies have failed to identify influenza viruses in donors drawn in U.S. communities during periods of high seasonal influenza activity or in donors with the onset of influenza-like illness immediately following donations.[22c] The current consensus is that pandemic influenza is not likely a threat to blood recipients, but that disruption of the blood supply in a severe pandemic is a more important possibility requiring careful advance planning.

Xenotropic Murine Leukemia Virus–Related Virus

The alleged association of the gammaretrovirus xenotropic murine leukemia virus–related virus (XMRV) with chronic fatigue syndrome/myalgic encephalomyelitis (CFS/ME) is paradigmatic of the difficulties inherent in the real-time assessment of potential and emerging transfusion-transmissible infections. A group of CFS/ME patients and controls were evaluated using polymerase chain reaction (PCR), virus isolation, serology, and immunohistochemistry.[20] Evidence of the virus's presence was strongly associated with the clinical diagnosis, culturable virus was found in plasma, and the issue of transfusion transmission was appropriately raised.

Multiple subsequent studies from other groups over the ensuing 2 years failed to confirm the presence of XMRV in a variety of populations. Several publications suggested that PCR contamination might underlie some positive results, and data now suggest that XMRV arose as a recombinant of two murine leukemia viruses during passages in nude mice, all suggesting the initial findings to be artifact.[21]

Absent definitive data or scientific consensus, an interdisciplinary task force from the transfusion medicine, research, advocacy, and regulatory communities was formed within 2 months of the original publication to assess potential risks to transfusion recipients and to identify policy alternatives.[22a] The U.S. blood community currently provides educational materials to prospective donors, asking those with a medical diagnosis of CFS/ME to refrain from donation at least while the data are accumulating. A scientific working group convened under the auspices of the National Heart, Lung, and Blood Institute (NHLBI) to establish a scientific agenda with reference to risks from transfusion and to facilitate appropriate research.

Two federal advisory committees, the Health and Human Services Secretary's Advisory Committee on Blood Safety and Availability and the Food and Drug Administration's Blood Products Advisory Committee held briefings and hearings during 2010 to 2011 to review the available data and make policy recommendations. By this writing a consensus has emerged that XMRV is not a human pathogen in either CFS or prostate cancer (where it had originally been described); however, concerns expressed by CFS/ME advocates and the two advisory committees have provided momentum for continued exclusion of these donors. The rationales are that donation may be harmful even to recovered CFS/ME patients and that donors with a history of CFS should be excluded on the general principle that it is a syndrome of unknown etiology that may pose some threat to transfusion recipients.

BACTERIAL CONTAMINATION

Bacterial contamination of red cell and platelet components occurs primarily as a result of incomplete skin disinfection at the donor phlebotomy site, where bacterial populations survive in skin appendages below the accessible surface and contaminate skin plugs made by the phlebotomy needle that enters the blood bag. Transient asymptomatic bacteremia at the time of blood donation, a break in technique during pooling the contents of or sealing blood containers, disruption of blood bag integrity or its contamination during manufacturing are other rare sources. Bacterial proliferation occurs more rapidly in platelet concentrates stored at room temperature than in red cells maintained at 4° C (39.2° F).

The rate of bacterial contamination in allogeneic platelets was estimated at 1 per 1000 to 3000 units with life-threatening septic reactions occurring in 1 per 15,000 to 100,000 recipients before routine implementation of culture-based tests to detect bacteria in apheresis platelets in 2004. These tests reduced contamination rates to approximately 1 per 5000 to 8500 platelet units. Clinical septic reactions occur in approximately 30% of recipients receiving

contaminated platelets. Bacterial contamination was responsible for 33 of 267 transfusion-related deaths reported to the FDA from 2005 to 2009.[23] Only acute hemolytic reactions and transfusion-related acute lung injury (TRALI) were responsible for more. Further, there is consensus that these reactions are badly underrecognized and underreported. Culturing fails to detect 50% to 75% of contaminated units. This undetected contamination occurs largely because minimal bacterial levels present when cultures are obtained yield culture aliquots without bacteria. Subsequently the few bacteria remaining in the blood bag can grow out during storage, producing transfusions with significant bacterial levels. To minimize this, collection facilities generally hold apheresis platelets for approximately 24 hours after collection before sampling for culture to allow low bacterial inocula to proliferate, improving the sensitivity of culture. In addition, improved skin antisepsis and diversion for laboratory testing of the first 15 to 30 mL of blood, which contain the skin plug, provide further reduction of contamination rates, transfusion reactions, and fatality rates by lowering the bacterial load that otherwise would enter the final component container.

Septic transfusion reactions should be suspected when one or more of the following occur within 1 to 4 hours of transfusion: temperature elevations greater than 1° to 2° C (1.8° to 3.6° F), chills and rigors, tachycardia more than 120 beats per minute or an increase of 40 beats per minute, or an increase or fall in systolic blood pressure of greater than 30 mm Hg. Additional signs and symptoms can include nausea, vomiting, diarrhea, bleeding, oliguria, or septic shock. Septic transfusion reactions may be confused with hemolytic transfusion reactions, febrile, nonhemolytic transfusion reactions, or TRALI.

Platelet concentrates contaminated with *Escherichia coli*, *Staphylococcus aureus, Staphylococcus epidermidis*, *Serratia marcescens*, and *Streptococcus* species account for most fatal reactions. *Propionibacterium acnes* is a frequent culture isolate from platelets during storage but is not believed to be responsible for a significant number of reactions. The bacterial dose in platelet concentrates and species virulence correlate with the clinical outcome. Bacterial concentrations greater than 10^6 colony-forming units (CFU)/mL are more likely to result in severe reactions or fatalities. Alternatively, low concentrations, 10^4 or fewer CFU/mL of skin organisms, frequently elicit no reaction. Endotoxin elaboration by gram-negative organisms is associated with the most severe reactions.

In addition, bacteria grow at variable rates. *S. epidermidis* grows slowly, and *P. acnes* requires on average 69 hours for detection. Because collection agencies continue bacterial culturing until the platelet unit expiration date or detection of growth, there is further opportunity to intercept released platelets that have not been transfused and to alert physicians about the potential risk for bacterial contamination in cases where the units have been administered. However, the vast majority of septic reactions are associated with false-negative culture tests due to sampling insufficiency as noted earlier.

Before the mid-1980s, platelet concentrates were stored for 7 days. Following reports of septic reactions, the shelf life was reduced to 5 days to decrease the interval during which bacteria could proliferate. In the United States, blood suppliers distributed platelets from 2005 to 2008 with a 7-day shelf life following enrollment in an FDA-mandated postmarket surveillance study (Post Approval Surveillance Study of Platelet Outcomes, Release Tested [PASSPORT]) that included testing for bacterial contamination by a sensitive culture method. Initial experience suggested that extended platelet storage coupled with bacterial testing substantially decreased platelet loss from outdating. However, the PASSPORT study found 1 per 4329 tested platelet products with negative bacterial cultures had bacterial growth when tested at the end of storage, 7 days later.[24] Septic reactions occurred in approximately 1 per 25,000 platelet transfusions; some following infusion of 3-day stored platelets, most with those stored 4 days or longer, leading to reinstatement of the 5-day platelet shelf life.

Alternative methods for detecting bacterial contamination include point-of-release testing in the hospital transfusion service. Considered a supplement to culture-based testing, this assay can be used shortly before issuing platelets for transfusion to detect units missed by early culture. This rapid qualitative immunoassay tests for the presence of conserved bacterial antigens (gram-negative lipopolysaccharide and gram-positive lipoteichoic acid). In one report using this test, 1 per 3000 platelet doses contained gram-positive organisms when issued 3 or more days after collection.[25] Other methods, under development, for mitigating septic platelet events include microcolorimetry, bacterial spore biosensors, real-time PCR, flow cytometry, and detection of other bacterial cell wall constituents. Pathogen-reduction technology using psoralens or riboflavin plus UV light provides an opportunity for inactivating multiple pathogens before they can proliferate.

Red blood cell bacterial contamination rates approximate 1 per 30,000 units with adverse clinical outcomes occurring in 1 per 500,000 transfusions and fatalities occurring at a rate of 1 per 10 million. Most septic reactions occur in units stored for 4 weeks or longer, reflecting the delayed growth of bacteria at 4° C (39.2° F).

Bacteria isolated from contaminated red cell units include *S. marcescens, E. coli, Pseudomonas* species (especially *Pseudomonas fluorescens*), and *Yersinia enterocolitica.* The latter two are psychrophilic and well known to proliferate in the cold. Gram-positive skin saprophytes account for most of the organism-contaminating platelet concentrates, with the remaining attributed to gram-negative organisms associated with occult bacteremia.

Immediate recognition of a platelet or red cell septic reaction and immediate discontinuation of the transfusion, supportive care, and antibiotic administration are the mainstays of therapy. Prevention relies on careful donor selection and scrupulous adherence to aseptic techniques and precautions from component collection, processing, transport, and storage to transfusion at the bedside. The Gram stain reveals bacteria in platelet concentrates contaminated with more than 10^5 to 10^6 CFU/mL.

Donors of platelet units contaminated with *Streptococcus bovis* or *Streptococcus infantarius* have been associated with colonic polyps and colon cancer.

SPIROCHETE INFECTIONS

Syphilis

U.S. blood banks first screened donors with a serologic test for syphilis in 1938, and screening has been a regulatory requirement since 1958. It was the first test mandated for U.S. donors and stood alone before the discovery of the Australia antigen almost two decades later. More than 100 transfusion syphilis cases were published before World War II, and many more certainly occurred. The last alleged case of transfusion-transmitted syphilis in the United States, however, was in 1966. Since then, hundreds of millions of components have been transfused in this country without another recognized case. There are multiple explanations for the disappearance of transfusion-transmitted syphilis in addition to testing: (1) the dramatic decline in the incidence of early syphilis in the United States over the decades, more than an order of magnitude, reducing the reservoir of donors able to transmit; (2) the end of direct donor-to-recipient transfusion combined with the loss of viability of *Treponema pallidum* in stored blood—the latter attributed to poor survival in refrigerated red blood cells and to the high oxygen tension in platelets stored at higher temperatures; (3) the ubiquitous administration of antibiotics for trivial to serious viral, bacterial, and noninfectious clinical syndromes, especially to those sick enough to be transfused; (4) donor deferral for behavioral correlates of syphilis risk (e.g., male sex with males, occurrence of recent sexually transmitted infection in donors, exchange of drugs or money for sex, injection drug use); (5) passive surveillance for transfusion-transmitted syphilis compounded by the failure of recognition by physicians (who may have never seen syphilis, venereal or otherwise); and (6) donor illness during spirochetemia severe enough to prevent their presentation to donate blood or causing deferral. The relative contributions of each of these factors are unquantified.

Most blood collection facilities screen donors with an automated test for detecting treponemal antibodies (e.g., *T. pallidum* hemagglutination assay[TPHA]) and confirm reactive assays using reference methods like the *T. pallidum* particle agglutination (TPPA) assay or fluorescent treponemal antibody, absorbed (FTA-abs) test. Approximately 50% of donors with confirmed positive test results have evidence of a treated syphilis infection. Donations with reactive syphilis tests are generally discarded. Blood centers defer donors with positive confirmatory tests for 1 year and then may restore donor eligibility after the donor provides evidence of appropriate treatment for syphilis and has a negative nontreponemal serologic test result. Persistent false-positive reactions on nontreponemal tests (e.g., rapid plasma reagin [RPR]) occur in healthy donors and with a wide variety of infectious diseases other than syphilis, after some immunizations, with autoimmune disease and other chronic inflammatory disease, and have increasing prevalence with increasing age.

The vast majority of contemporary reactive STS results in donors are biologic false positives, unrelated to syphilis, especially where nontreponemal assays are used (<1% confirmed during 2008, data on file Mississippi Valley Regional Blood Center). Many true positives are the "serologic scar" of remote (often treated) infection and pose no risk to blood recipients. A recommendation to discontinue donor screening for syphilis was made in 1985 but not acted upon initially because of the perception that the STS might be functioning as a surrogate for HIV or other transfusion-transmissible viruses.[26] This hypothesis has been rejected, but, because the role of STS in the elimination of transfusion syphilis is unclear, syphilis testing continues. Although small PCR studies of reactive donors have been universally negative, rabbit inoculation studies using samples from confirmed reactive donors will likely be required to eliminate syphilis testing, and it seems unlikely the resources will be found to do a study of the required size.

Lyme Disease

Borrelia burgdorferi is the spirochete that causes Lyme disease, the most frequent vector-borne infection in North America and Europe. The agent was discovered in 1977 during investigations of an arthritis cluster in Connecticut children. Cases reported in the United States doubled between 1992 and 2006 to almost 20,000. Geographic distribution of cases is highly focused with the majority of reported cases occurring in 10 northeast and north central states. *Ixodes scapularis*, the black-legged tick, transmits *B. Burgdorferi* in those areas, and *Ixodes pacificus*, the western black-legged tick, transmits the infection along the Pacific coast. The ticks feed predominantly in late spring and early summer during the nymph stage. Emergence has been associated with environmental changes that increase deer and rodent reservoir populations and changing residential patterns putting humans in more intimate contact with the tick vectors. Rodents are the reservoir. Although deer are not infected, they transport and maintain the ticks. Birds may also play a role in transporting the vector ticks.

The characteristic erythema chronicum migrans ("bull's-eye") rash is present in 70% to 80% of cases within 30 days of infection. The wide variety of clinical findings includes malaise, fatigue, headache, myalgias, large joint arthralgias and arthritis, and neurologic and cardiac signs and symptoms. These may not immediately suggest Lyme disease in the absence of a typical rash or known tick exposure. Serologic testing supports the clinical diagnosis. Unfortunately, poor specificity is recognized with many screening methods, and a two-step approach using a sensitive EIA or immunofluorescence assay (IFA) followed by a confirmatory, more specific, immunoblot is recommended by the Centers for Disease Control and Prevention.

B. burgdorferi spirochetemia occurs in 44% of patients with clinical Lyme disease and peaks 7 to 10 days after tick bite. The spirochete can survive in red cells, platelets, and frozen plasma for at least the duration of their routine storage. Transfusion transmission of *B. burgdorferi* has been demonstrated in a murine model. Despite these observations, no human transfusion-associated cases have been reported. This may reflect the relatively short spirochetemic phase and deferral of donors with nonspecific illness or signs and symptoms of Lyme borreliosis. Although there are no official standards or guidance, it would be prudent for individuals with a history of Lyme disease to be deferred until well and treatment has been completed.

Other Tick-Borne Bacteria

The rickettsia that cause human monocytic ehrlichiosis (HME) and human granulocytic anaplasmosis (HGA; formerly human granulocytic ehrlichiosis) are intracellular bacteria that survive in stored blood. *Ehrlichia chaffeensis* causes HME and is transmitted to humans by Lone Star tick (*Amblyomma americanum*) bites. Most cases occur in the south central and southeastern United States. *Anaplasma phagocytophilum* causes HGA and occurs predominately in the northeastern and upper midwestern areas of the United States. *I. scapularis* and *I. pacificus* (the Lyme borreliosis vector) transmit the organism. Signs and symptoms include fever, chills, and headache, often associated with thrombocytopenia, leukopenia, and increased liver enzyme levels. Intracellular aggregates appear in monocytes in the HME, and inclusions appear in granulocytes in HGA. Seroprevalence studies in blood donors in Wisconsin and Connecticut report 0.5% to 3.5% seropositivity for *A. phagocytophilum* antibodies.

Two cases of transfusion-transmitted HGA from asymptomatic donors have been recognized after nonleukoreduced RBC transfusion. The RBCs had been stored for 30 and 15 days before transfusion. In a study of heavily tick-exposed military recruits in Arkansas, which included a look back to 10 blood recipients of units from soldiers infected with *E. chaffeensis* and *Rickettsia rickettsii* (the agent of Rocky Mountain spotted fever [RMSF]), no clinical illness occurred in recipients. One possible RMSF seroconversion was reported.

There is a single case report of transfusion-associated RMSF that involved a donor developing symptoms 3 days postdonation. The recipient developed symptoms 6 days posttransfusion.

Both *Ehrlichia* and *Anaplasma* spp. are white blood cell–associated, and leukoreduction has been proposed to mitigate their impact. The infectivity of *Orientia tsutsugamushi*, the rickettsial agent of scrub typhus, is reduced by up to 10^5 by filtration leukoreduction, but infectious *E chaffeensis* survived in refrigerated red cells and could be isolated from the packed RBCs after filtration. Tick-borne RBC pathogens like *Babesia* and Colorado tick fever virus are unlikely to be affected by leukoreduction.

PARASITIC INFECTIONS

Malaria

Five *Plasmodium* species (*Plasmodium falciparum, Plasmodium vivax, Plasmodium ovale, Plasmodium malariae and Plasmodium knowlesi*) and occasionally others cause the protozoan disease malaria. In 2008, 243 million cases occurred worldwide, with most in sub-Saharan Africa. Other endemic areas include parts of Asia and South America and more limited areas in Mexico, Central America, and the Caribbean. Of 1478 imported cases in the United States in 2009, 735 were acquired in Africa, 142 in Asia/Western Pacific, and 103 in the Americas.[27] West Africa accounted for most cases associated with Africa, and Honduras, Haiti, and Guyana for most of the cases from the Americas. During 2009, only two cases were acquired in Mexico, both *P. vivax*. In 2003, eight autochthonous infections occurred in Palm Beach, Florida; but none subsequently. Vectorial transmission, overwhelmingly the most common route, is by the bite of an infected female *Anopheles* mosquito. *Anopheles* mosquitoes generally feed between dawn and dusk, thereby limiting the risk to tourists who usually visit malaria areas during daylight hours. Almost three-quarters of those who acquired malaria were visiting friends or relatives in endemic areas. Missionaries and business travelers represent

fewer than 20% of infected U.S. citizens. Leisure travelers make up the small remainder. Two other routes are more rare, congenital and induced malaria. The latter includes the intentional parenteral transmission of malaria as was done for treatment of neurosyphilis in the remote past and more recently for Lyme borreliosis, transmissions during injection drug use, and transmission by transfusion.

P. falciparum accounts for 40% to 46% of U.S. cases detected recently, *P. vivax* 11% to 20%, and *P. malariae* and *P. ovale* approximately 2% each. For the remainder most are undetermined with a few mixed-species infections. *P. knowlesi* has not yet been reported.

Seventy percent of imported cases in the United States occurred among returning travelers who were visiting friends or relatives, ethnically and racially distinct from the majority population of the United States (where malaria is not endemic), who return to their homelands (countries where malaria is endemic) to visit friends or relatives. The region of origin is very relevant to measures designed to prevent malaria transmission by transfusion because many of these individuals are semi-immune and therefore can be parasitemic while asymptomatic. In contrast, donors without malarial immunity who travel to endemic areas and become infected are nearly always symptomatic when they are parasitemic and would not be accepted as blood donors. Malaria symptoms occurred within 1 month of arrival in the United States in 84% of those infected with *P. falciparum* and 56% of those with *P. vivax* in 2009. The latter represents almost all cases of relapsing malaria. No acute onsets involving the four most frequent *Plasmodium* species occurred at an interval greater than 1 year.

Ninety-eight transfusion cases have been recognized and reported in the United States since 1963. During the past 10 years there have been 17 (0 to 3 per year) including 1 in 2007, none in 2008, and 2 in 2009. In the majority of these 98 the case would have been prevented had the extant donor deferral criteria been appropriately applied.

The incubation period for transfusion-associated malaria ranges from 8 to 90 days. *P. falciparum* has the shortest time, mean 17 days (range, 8 to 36 days) and *P. malariae* the longest, mean 50 days (range, 8 to 90 days). Most cases involved RBC or whole-blood transfusion, although a few transmissions from platelet transfusions have occurred, presumably related to RBC contamination. Transmission from frozen plasma has not been reported.

Current strategies for reducing the low risk for transfusion transmission in the United States involve deferral of residents of nonendemic areas who have traveled to malaria-endemic regions during the previous 12 months, those with residence in endemic areas for 3 years since their last potential exposure in such regions, and those with a history of malaria for 3 years after resolution. Apart from incomplete elicitation of malaria risk history, residual risk remains because transfusion transmissions of *P. falciparum*, *P. vivax*, and *P. ovale* have been reported 13, 27, and 7 years, respectively, after departure from malarious areas. Because *P. malariae* infection can persist for more than 70 years without symptoms, elimination of transfusion-induced malaria is a practical impossibility. At this time, licensed in vitro screening for at-risk donors using antibody tests, antigen detection, or NAT are unavailable in the United States. It is not clear that the limited commercial potential of assays to be used on a relatively small fraction of donors will justify the investment required to pass the stringent regulatory requirements of a blood donor screening assay. Donor deferral guidelines are undergoing review to reduce the loss of more than 60,000 potential donors with travel to areas of Mexico where the malaria risk is minimal. Removing the restriction for these donors would increase donations and might promote greater attention to more effective screening or travelers at higher risk.[28]

Babesiosis

Babesia species that infect humans include *Babesia microti*, *Babesia duncani* (previously WA1 type), *Babesia divergens* (limited primarily to Europe), *B. divergens*–like (MO1 and EU1), and *Babesia venatorum*. *B. microti*, an intraerythrocytic protozoan, causes most human infections. The white-footed mouse, *Peromyscus leucopus,* serves as the reservoir and the deer or black-legged tick, *I. scapularis* (also the vector of Lyme borreliosis and HGA), as the vector. Transmission follows bites from infected ticks, primarily nymphs, from May through early September. The defined transmission period has less relevance for transfusion transmission because asymptomatic blood donors can be infected chronically.[29] Most cases occur in Massachusetts and its coastal islands, Rhode Island, Connecticut, New York, New Jersey, Wisconsin, and Minnesota. This geographic range has expanded recently, attributed to expansion of white-tailed deer, *Odocoileus virginianus,* populations. Although not a competent host, deer provide a blood meal and transportation for adult ticks to new areas.

The vast majority of both vectorial and transfusion-associated *Babesia* cases involve *B. microti. B. duncani* infections include those previously designated WA1. *B. divergens* cases occur predominately in Europe. Most infected patients had splenectomies before infection. Cattle serve as the reservoir and *Ixodes ricinus* ticks the vector. There are no reports of transfusion-associated *B. divergens* infections.

The incubation period varies from 1 to 9 weeks. The severity of illness associated with *Babesia* infections relates more to the infected individual's immune status than the *Babesia* species. The very young, older adults, persons who have had a splenectomy, and those with hereditary hemolytic disorders are at greatest risk for morbidity and mortality. Approximately one-third of infected subjects remain asymptomatic, and parasitemia may persist for more than 2 years. Typical symptoms resemble malaria and include fever, headache, chills, sweats, and arthralgia, myalgia, malaise, nausea, diarrhea, and hemolytic anemia. Parasitemia levels vary from 1% to 2% in otherwise healthy hosts to 85% in immunocompromised and asplenic patients. Case fatality rates approximate 5%.

Case reports of transfusion-associated *Babesia* infections include units stored for 35 days. *Babesia* transmission has been reported following transfusion of cryopreserved red cells, and four cases involve whole blood–derived platelet transfusions presumably contaminated with red cells. At least 159 transfusion-associated *B. microti* cases have occurred, primarily in endemic regions, but cases in nonendemic states reflect the interstate movement of both blood components and blood donors and highlight the high index of suspicion required to recognize cases.[30] More than three-quarters of the reports occurred during the past decade. The all-cause mortality rate approaches 19%. There are three cases involving *B. duncani,* and single cases have been reported from Japan (*B. microti*-like) and Germany.

Risk estimates of transfusion transmission vary over such an extremely wide range as to provide little utility. They are likely to be underestimates due to failure to recognize the infection or its relationship to a recent transfusion. Babesiosis has been made a nationally notifiable infection and included in the nascent biovigilance network of the National Healthcare Safety Network, so more accurate measurements of transfusion risk may become available in the future.

Febrile patients must be queried for a transfusion history and babesiosis considered when transfusion has occurred. Diagnostic laboratory evaluation includes blood smear examination, which requires differentiation of *Babesia* sp. from *Plasmodium* infections. Tetrad or "Maltese cross" forms are diagnostic for *Babesia* but occur infrequently. Serologic testing is under development. Indirect immunofluorescence antibody testing is the current test of choice for identifying persons with low-level parasitemia such as patients with chronic infections but may remain positive after resolution or cure of babesiosis. PCR testing may be more sensitive for detecting acute infections before seroconversion.

In the absence of an FDA-licensed test, mitigation of transfusion transmission involves deferral of potential donors with a history of *Babesia* infection. Questioning donors about tick exposure or tick bite has no predictive value as a donor-screening question. One blood center conducts tests under an IND exemption using IFA and NAT to screen donations intended for immunosuppressed patients considered at highest risk for *Babesia* infection complications such as neonates, pediatric patients with sickle cell disease, and pediatric oncology patients. IFA is being used by another system in highly endemic regions. An attractive alternative is the adoption of pathogen-reduction technologies.

Leishmaniasis

Phlebotomine (Old World) and *Lutzomyia* (New World) sand-fly bites transmit *Leishmania* infections to humans in most of the tropical and subtropical world. Trypanosomatidae of various species cause visceral infection (*Leishmania donovani, Leishmania infantum,* and others, kala-azar) and cutaneous and mucocutaneous infections (*Leishmania tropica, Leishmania major, Leishmania mexicana, Leishmania braziliensis,* and others that go by a variety of local names). In addition, transplacental, sexual, and transfusion transmissions occur.[31] The promastigote form of the parasite resides in the gastrointestinal tract of sand flies and is inoculated into humans through a skin bite. In humans, promastigotes are phagocytosed by monocytes, where they transform into amastigotes that reproduce and reside in macrophages and the reticuloendothelial system. Organisms in monocytes and free amastigotes are released during refrigerated storage, transform back into extracellular promastigotes, and mediate transfusion transmission. *L. tropica* also survives in monocytes contained in frozen red cell preparations and in platelet concentrates stored at room temperature. At least 10 cases of transfusion-associated leishmaniasis attributed to *L donovani* have been reported in endemic areas, mostly in young children or neonates. A probable case of platelet transfusion–transmitted *L. donovani* was reported in India. A presumed case of transfusion-transmitted *L. mexicana* in a renal transplant recipient was mistakenly diagnosed as Chagas disease because of serologic cross-reactivity between *Trypanosoma cruzi* and *Leishmania. L. infantum* DNA was amplified from 6% of peripheral blood mononuclear cells of blood donors with *Leishmania* antibodies in the Balearic Islands. Several animal model studies also demonstrate transmission by blood transfusion.

Asymptomatic infections occur frequently in healthy donors exposed in endemic areas, and the organisms may circulate in peripheral blood more than 1 year following exposure. Foxhounds infected with *Leishmania* species have been found in 18 U.S. states and 2 Canadian provinces, but transmission has not extended to humans.

Following reports of *L. tropica*–related viscerotropic leishmaniasis in veterans of Operation Desert Storm, between August 1990 and December 1992, those serving in that theater of operations were deferred from blood donation for 1 year. The deferral period reflected the development of fever, malaise, abdominal pain, and intermittent diarrhea up to 7 months after return to the United States. *L. tropica* was found in the bone marrow of seven patients and in the lymph nodes in one. When intracellular amastigotes were seen in the peripheral blood of the one patient in whom this was studied following reports of cutaneous and visceral leishmaniasis among troops involved in the Afghanistan and Iraq wars, a similar 1-year deferral following departure from Iraq and Afghanistan was implemented. The military continues to enforce lifetime deferral for any clinical history of *Leishmania* infection.

The possibility of transmission to humans during military deployment and travel and the large number of military personnel returning from Iraq and Afghanistan raise concerns about future transfusion transmission. To date, there are no cases of transfusion-transmitted leishmaniasis in the United States. The widespread use of leukocyte reduction filters may have a beneficial role because these filters reduce both intracellular and extracellular parasite concentrations by 3 to 4 logs.

Toxoplasmosis

Toxoplasmosis is caused by the obligate intracellular protozoan parasite *Toxoplasma gondii*, whose usual host is the domestic cat. The parasite is transmitted by exposure to cat feces, by eating raw or undercooked pork, goat, lamb, beef, or wild game, and congenitally. In NHANES (1999-2004) 24.8% of foreign-born U.S. residents age 12 to 49 years of age, compared with 8.2% of U.S.-born residents, had serologic evidence of infection and perhaps half with antibody harbor parasites in tissue. Transfusion-associated disease has been described in immunocompromised patients receiving granulocyte concentrates from donors with chronic myelocytic leukemia who would not qualify as blood donors currently. One possible transfusion-related case involves a platelet transfusion. Red cells and frozen plasma transmission have not been reported.

Chagas Disease

The protozoan parasite *T. cruzi* causes Chagas disease. The infection is widespread in Latin America; approximately 8 to 10 million people are affected worldwide. Humans become infected when bitten by *T. cruzi*–infected insects of the Reduviidae family (triatomine, assassin, kissing, or chinch bugs). Congenital transmission from mother to fetus, organ transplantation, and blood transfusion are recognized routes as well. Once infection occurs, low-level, intermittently detectable parasitemia usually persists for life. Treatment with benznidazole or nifurtimox can reduce the risk for chronic sequelae. Eighteen mammalian species in the United States can be infected, including armadillos, opossums, and raccoons, and vectors are present in the lower two-thirds of the country, but autochthonous vector transmission is rare. An estimated 300,000 people in the United States and Canada are infected with *T. cruzi*; most are immigrants from Latin America. *T. cruzi* organisms remain viable in whole blood stored at refrigerator temperatures for 18 days, for longer than 8 months in citrated blood samples stored at room temperature, and following freezing and thawing. In South America, approximately 13% to 49% of recipients of parasitemic blood become infected. There has been concern that additional transfusion-associated Chagas disease cases will occur as immigration increases to the United States from Central and South America.

American trypanosomiasis, or Chagas disease, consists of an acute phase that varies from asymptomatic to manifestations that include fever, skin rash, and conjunctivitis with palpebral edema, lymphadenopathy, and hepatosplenomegaly. The acute phase usually resolves in 4 to 8 weeks unless severe myocarditis or meningoencephalitis intervenes. The latter is associated with fatal outcomes. Intracellular *T. cruzi* amastigotes remain in cardiac and skeletal muscle following the acute phase. Following an indeterminate stage of undetermined duration, chronic disease occurs in 20% to 30% of infected patients, manifesting as cardiac disease (initially conduction and left ventricular wall abnormalities), megacolon, or achalasia. Diagnosis is made on clinical and serologic grounds most often. Xenodiagnosis, hemoculture, and nucleic acid amplification tests are also available.

Risk factors for transfusion-transmitted *T. cruzi* infection include birth or residence in endemic regions such as Central America, South America, or Southeastern Mexico; living in dwellings with palm leaf–thatched roofs or mud walls, where vector insects reside; oral intake of contaminated foodstuffs; and receipt of unscreened blood transfusions in Latin America. Among donors who lived in poor housing or received a blood transfusion in endemic areas, 3% to 4% had *T. cruzi* antibodies. One study, conducted in California in the 1990s, found that 1 per 340 blood donors had a risk factor for Chagas disease. A large survey conducted from 1994 to 1998 in Los Angeles and Miami among immigrant blood donors from endemic areas found *T. cruzi* seroprevalence rates of 1 per 7500 and 1 per 9000, respectively. However, none of the 18 recipients in this survey who received blood from a seropositive donor, and who were available for testing, had evidence of infection.

A look-back study involving blood donations in Mexico made before determining the donors were *T. cruzi*–seropositive, found four of nine recipients of subsequently determined seropositive whole blood or platelets to be seropositive.

Since 1987, 30 years before testing started in the United States, seven cases of transfusion-associated Chagas disease were reported in the United States and Canada; symptoms developed 2 to 3 months after transfusion. In six cases, platelets were the implicated component; and the unit in the seventh case was not identified. In each of the six cases, the implicated donor emigrated from a *T. cruzi*–endemic region (Bolivia, Mexico, Paraguay, and Chile) between 16 and 33 years before the implicated donation. *T. cruzi* may separate with

platelets, or room-temperature storage may favor parasite survival. In addition, acute Chagas disease has been reported in organ transplant recipients.

The assumed increasing prevalence of *T. cruzi*–infected blood donors with immigration into the United States from Latin America, the reports of transfusion-associated cases, and some autochthonous infections triggered efforts to mitigate the risk for transfusion-transmitted Chagas disease in the United States. Questioning donors about region of birth or extended stay and transfusion in Chagas-endemic areas interdicts 75% of infected donors but would result in deferral of large numbers of noninfected donors. Leukocyte reduction by filtration decreases *T. cruzi* transmission in a mouse model by 50% to 70%. Pathogen-reduction techniques successfully decrease *T. cruzi* viability in plasma (used currently in Europe) and cellular products.

Serologic screening, used for many years in Latin America, was chosen as the preferred strategy for the United States. The first serologic test for screening blood donors, based on a *T. cruzi* whole-parasite lysate, achieved FDA licensure in December 2006, and voluntary screening commenced in early 2007. Approximately 1 per 30,000 donations showed confirmed reactive serologic results, a lower prevalence than estimated. In 2010, the FDA licensed a second assay that uses chimeric recombinant antigens. Seropositive donors are overwhelmingly immigrants from *T. cruzi*–endemic countries with asymptomatic chronic infections, although a small number of seropositive donors may have acquired the infection in the United States via vertical transmission from infected immigrant mothers, or very rarely by autochthonous vectorial transmission.

Look-back studies involving recipients of prior donations from those found positive for *T. cruzi* antibodies on a subsequent donation showed rates of transfusion transmission much lower than predicted. Only two occurred (0.8%), both from the same apheresis platelet donor born in Argentina, among 253 recipients tested. In light of these findings, testing donors is now required only once rather that at each donation.[32] Concern that those tested once might contract *T. cruzi* during travel or within the United States seems unfounded in that no seroconversions have been observed in more than 4 million blood donors during 6 million person-years of follow-up. The unexpectedly low rate of transmission may relate to differences in blood component processing and storage in the United States compared with Latin America, some underrepresentation of platelet donors in the look backs completed to date, or other biases.

TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES

The transmissible spongiform encephalopathies (TSEs, prion diseases) are rare, lethal neurodegenerative diseases caused by nucleic acid-free proteins called PrP^{TSE}, as distinguished from the normal cellular protein, PrP^{C}. The existence of additional factors has not been excluded, but current consensus supports the involvement of infectious proteins. PrP^{TSE} is an abnormal conformation of PrP^{C} that induces transformation (recruitment) of additional PrP^{C} to PrP^{TSE}, resulting in deposits of insoluble aggregates in central nervous system tissue followed by progressive dementia and other characteristic neurologic findings. Classic Creutzfeldt-Jakob disease (CJD) is diagnosed at a rate of one case per million population per year worldwide. It occurs as sporadic CJD, vertically transmitted familial diseases caused by germline mutations in the human PRNP gene (e.g., fatal familial insomnia and Gerstmann-Straüssler-Scheinker syndrome), iatrogenically transmitted infection (e.g., from dura mater implantation, contaminated surgical equipment, injection of human pituitary-derived growth hormone, or corneal transplant) and can be spread horizontally (Kuru associated with consumption of human brain during ritual cannibalism is of historical interest).

There are no documented cases of transfusion transmission of sporadic CJD, the familial or iatrogenic forms, and cohort studies of intensively transfused patient groups have failed to establish any epidemiologic association. In an ongoing look-back effort, no cases of CJD have been observed among 461 recipients (of whom 85 were still alive as of December 31, 2008) of blood components from 40 donors subsequently diagnosed with CJD. A case-control study of CJD patients, compared to control patients with CJD ruled out, found a fivefold increased risk for CJD with a history of transfusion more than 10 years before TSE onset, but the authors recognized critical sources of bias in their methods and their findings are unconfirmed. Nevertheless, as a result of the iatrogenic transmissions and long incubation period of the disease (as demonstrated in growth hormone transmissions), concern arose in the mid-1990s that CJD transmission could occur from asymptomatic donors to transfusion or derivative recipients. This theoretical risk resulted in lifetime donor deferral requirements for iatrogenic exposure to or a family history of classical CJD.

Like classical CJD, variant CJD (vCJD) is a fatal, degenerative neurologic disease. It occurs in younger patients than classic CJD and has distinctive clinical, radiographic, histopathologic, and biochemical features. The first reports of vCJD from the United Kingdom were published in 1996. The etiologic agent is the same prion that causes bovine spongiform encephalopathy (BSE or "mad cow disease"). Transmission of the BSE prion to humans occurred by consumption of beef and other bovine products containing infectious neural or reticuloendothelial tissue. In the United Kingdom the vCJD epidemic followed a massive epidemic of BSE in the 1980s and 1990s. The latter was traced to the recycling of material from dead sheep and cattle (offal) into feed for cattle. This practice was banned in 1988, and the vCJD outbreak subsided after a peak of 28 cases in 2000. The number of new vCJD diagnoses in the United Kingdom rose steadily in the first few years after 1995 from 3 in 1995 to 28 in 2000, but decreased since then to 5, 5, 5, 1, 3, 3, and 2 from 2005 to July 2011, by which time 175 (172 deaths, 3 living) definite or probable cases of vCJD had been reported in the United Kingdom. An additional 49 cases have been diagnosed elsewhere, mostly in France and several other European countries. A few cases have been identified outside Europe, including 3 cases in the United States (2 associated with exposure in the United Kingdom and 1 in Saudi Arabia), 2 from Canada, and 1 each from Japan, Taiwan, and Saudi Arabia. Most but not all of the patients with non-European cases had more than 6 months' exposure in the United Kingdom during the BSE epidemic. Although it appears that the vCJD outbreak is waning (and is much smaller than initially feared), concern persists that there could be a second wave of the epidemic due to delayed onset of the disease in infected individuals. This is based in part on observations of abnormal prion protein accumulation in random surgical tissue samples in the United Kingdom, which may represent preclinical vCJD disease. In one retrospective study, 3 of 12,674 appendectomy and tonsillectomy specimens from persons 20 to 29 years of age were positive. Furthermore, a critical polymorphism at codon 129 of the PrP^{C} gene coding for methionine or valine leads to variation in the susceptibility to and incubation period of human TSEs. All of the clinical cases reported to date are methionine homozygotes. Because only 37% of the general British population is homozygous for methionine, and are maximally susceptible to vCJD, a larger population (52%) of heterozygotes and valine homozygotes (11%) may be at risk for asymptomatic infection in a prolonged incubation period.

Four transfusion-transmitted infections with the vCJD prion have been reported in the United Kingdom. Although they may have developed vCJD independent of transfusion, this possibility is regarded highly unlikely based on epidemiologic and statistical considerations. Three of the four cases were diagnosed with clinical vCJD 6.5, 7.8, and 9 years after receiving non–leukocyte reduced red blood cells or a blood component from two different donors who developed clinical symptoms of vCJD 40 and 21 months after donating. These three with symptomatic disease were homozygous for methionine at codon 129. The fourth case was heterozygous (methionine/valine) and had no clinical signs or symptoms of vCJD at death from unrelated causes, but had abnormal prion protein aggregates in lymphoid (but not neural) tissues at autopsy and was considered to have preclinical infection. Five years before death the recipient received non–leukocyte reduced red blood cells from a donor who developed clinical vCJD 18 months after donating. These four cases represent

6% of the 66 U.K. recipients who received blood components from 18 different donors subsequently diagnosed with vCJD (and an estimated 23% of exposed methionine homozygotes). In light of these cases and animal transfusion experiments, TSE transmission and disease from transfusion is no longer regarded as a theoretical event. A single case report epidemiologically links exposure to plasma derivates to transmission to a recipient.

Prion-removal strategies (e.g., affinity filters) remain under evaluation, especially in the United Kingdom, but none is expected to be suitable for consideration for use in the United States in the immediate future. There are no blood donor–screening tests for vCJD, leaving risk mitigation dependent on removal of donors that could have asymptomatic infection. Initially, primarily on the basis of the prominent distribution of vCJD prion in reticuloendothelial tissue compared to classic PrP^{C}, on subsequent reports of animal and human infection by transfusion, and then on the early observation that nearly all cases of vCJD were associated with potential exposure in the United Kingdom or to U.K. bovine products, the FDA adopted and has modified donor-deferral policies sequentially since 1999.[33] The first called for indefinite deferral of donors who had spent more than 6 months in the United Kingdom from 1980 to 1996, before control of the food chain and of recipients of bovine insulin from the U.K. Models predicted that this would remove approximately 90% of the risk at a "cost" of deferring approximately 5% of otherwise eligible donors. These were subsequently expanded to include U.S. military personnel and their dependents who spent certain durations on bases in the European Union where U.K. beef was imported during the BSE epidemic and recipients of transfusions in the United Kingdom and France during the peak risk periods of their BSE epidemics. Experience at U.S. blood centers has largely confirmed the donor loss predictions of the FDA models. Exclusions for potential exposures in Saudi Arabia are under consideration.

Chronic wasting disease (CWD) of deer and elk is prevalent at rates as high as 15% in cervid populations in multiple areas of the United States and Canada. Concern has been expressed that, given the popularity of hunting, there may be risk for exposure to and infection with the CWD prion during handling or consumption of infected animals. Apparent clusters of classic CJD in hunters have been alleged, but on full evaluation have not been shown to have a relationship to the CWD agent. There is currently no plan to intervene for this theoretical risk in hunters who donate blood beyond hygienic measures when handling cervids or their tissues.

FUTURE DIRECTIONS

The residual risk for transmitting HIV, hepatitis B, and hepatitis C approaches 1 per 2 million units transfused, an extremely low rate. In contrast, platelet septic events occur at a frequency of 1 per 15,000 to 100,000 units. Transmission of known, emerging infectious agents such as dengue, *B. microti,* and those currently unrecognized remain problematic. Continued safety of the blood supply requires constant vigilance, early detection, reporting of untoward events, and excellent communication and cooperation between those providing blood components and those prescribing them.

TRANSFUSION MEDICINE IN HEMATOPOIETIC STEM CELL AND SOLID ORGAN TRANSPLANTATION

Richard M. Kaufman

HEMATOPOIETIC STEM CELL TRANSPLANTATION

The array of hematopoietic stem cell transplantation (HSCT) approaches used to treat patients with malignant or nonmalignant diseases has continued to grow in complexity. In concert, the scope of transfusion medicine has expanded to support the development of novel hematopoietic stem cell therapies. Hematopoietic stem cells are currently obtained from three sources: bone marrow (BM), mobilized peripheral blood stem cells (PBSCs), and umbilical cord blood (UCB). After harvesting, and before infusion into the patient, stem cell products undergo a variety of manipulations in the laboratory, ranging from simple processing (e.g., red blood cell [RBC] depletion, freezing) to sophisticated graft engineering (e.g., T-cell depletion, retroviral transduction). Like conventional blood components, hematopoietic stem cell products are prepared in rigorously controlled environments using good manufacturing practices.

The focus of this section is on the unique issues involved with providing optimal transfusion support to the HSCT patient. After myeloablative conditioning and stem cell transplantation, there is a 1- to 4-week period of pancytopenia when patients require multiple RBC and platelet transfusions. In general, the criteria for transfusion after HSCT mirror those of other clinical settings, but the magnitude of support required may be great. Frequent platelet transfusions are given to prevent bleeding, and as a result, alloimmunization and platelet refractoriness are important concerns. Switching of ABO blood groups occurs commonly in the allogeneic HSCT patient population, posing unique problems to the blood bank and transfusion service. Because HSCT patients are typically highly immunocompromised, strategies are needed to prevent transfusion-transmitted cytomegalovirus (CMV) disease and transfusion-associated graft-versus-host disease (TA-GVHD).

ENGRAFTMENT AND BLOOD COMPONENT SUPPORT AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION

The level of transfusion support required by a particular patient after HSCT is dictated largely by the kinetics of engraftment and subsequent hematopoietic reconstitution. A key parameter affecting the engraftment rate is the source of stem cells used (Fig. 122-1). In the 1990s, several randomized trials demonstrated the superiority of PBSC- over BM-derived stem cells in terms of faster platelet and neutrophil recovery for patients undergoing autologous HSCT.[1] More rapid recovery using PBSCs rather than BM was later documented in the allogeneic HSCT setting as well. On average, neutrophil recovery (neutrophil count $>0.5 \times 10^9$/L) occurs 2 to 6 days earlier when PBSCs versus BM are used as the source of stem cells. Similarly, platelet recovery (platelet count $>20 \times 10^9$/L) occurs 5 to 8 days earlier after PBSC transplantation than after bone marrow transplantation (BMT).[2] One reason for the faster engraftment of PBSC products is that the cellular composition of PBSCs and BM is very different. PBSC products contain approximately threefold more $CD34^+$ cells and 10-fold more mature T cells than BM products.

There is a strong relationship between the $CD34^+$ cell dose administered and the speed of hematopoietic recovery. Faster engraftment rates have translated into decreased blood component usage. For example, Haas et al[3] reported that autologous PBSC transplant patients given more than 2.5×10^6 $CD34^+$ cells/kg received significantly fewer platelet transfusions than patients receiving less than 2.5×10^6 $CD34^+$ cells/kg (median of 4 versus 13 platelet units). In addition to the higher numbers of $CD34^+$ cells in PBSC products, there are multiple qualitative factors that differ between PBSC- and BM-derived stem cells, including cell surface molecule expression, metabolic activity, clonogenicity, and cell cycle status.[4] What impact these factors have on engraftment remains incompletely understood.

Several clinical factors may affect the rate of hematopoietic recovery and transfusion requirements after HSCT. Accelerated platelet recovery has been associated with a higher pretransplantation platelet count and receiving a graft from a human leukocyte antigen (HLA)–identical sibling donor. Factors associated with delayed platelet recovery include prior radiation therapy, the presence of fever, hepatic venoocclusive disease, GVHD, and the use of posttransplantation granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor. The use of recombinant human erythropoietin (rHuEPO) has been shown to accelerate RBC recovery and decrease RBC transfusion requirements among allogeneic HSCT patients. The particular conditioning regimen that is used also affects hematopoietic recovery. In particular, nonmyeloablative transplantation protocols predictably result in decreased transfusion requirements.[5]

Although PBSC products are currently the most commonly transplanted source of stem cells, the use of UCB transplants for both pediatric and adult recipients has continued to grow rapidly. One reason is that only about 30% of patients requiring HSCT have an HLA-matched related donor. Precise HLA matching has been demonstrated to be significantly less important for UCB products than for BM or PBSCs. Also, UCB transplants are associated with a lower rate of GVHD. A primary disadvantage of UCB is the lower $CD34^+$ cell content of these products. The currently accepted minimum cell dose of a UCB unit is 2.0×10^7 nucleated cells/kg at the time of freezing, about one order of magnitude lower than the threshold for PBSC or BM transplant.[6] The lower cell content of UCB has been linked to significantly slower hematopoietic recovery. For this reason, UCB transplants using two (or sometimes more) grafts simultaneously are often performed, particularly in adult patients. Time to recovery aside, outcomes of transplants with UCB have compared favorably with BM. Rocha et al[6] reported that mortality was similar among adults with acute leukemia who received either HLA-mismatched UCB (n = 98) or HLA-matched BM (n = 584). Acute GVHD was lower among the UCB recipients. Laughlin et al[7] likewise found that among adult patients with leukemia, recipients of HLA-mismatched BM and HLA-mismatched UCB grafts had similar rates of treatment-related mortality, treatment failure, and overall mortality.

The growth in UCB banking has created the (potential) advantage of rapidly available grafts to patients requiring transplantation. The University of Minnesota, for example, has reported that the search for a UCB unit typically takes approximately 1 day, compared with 3 to 4 months for a PBSC or BMT donor. It is possible that the ability to provide UCB grafts quickly will translate into better patient outcomes, but this has not been proven to date. In recent years, considerable efforts have been made to standardize UCB-banking

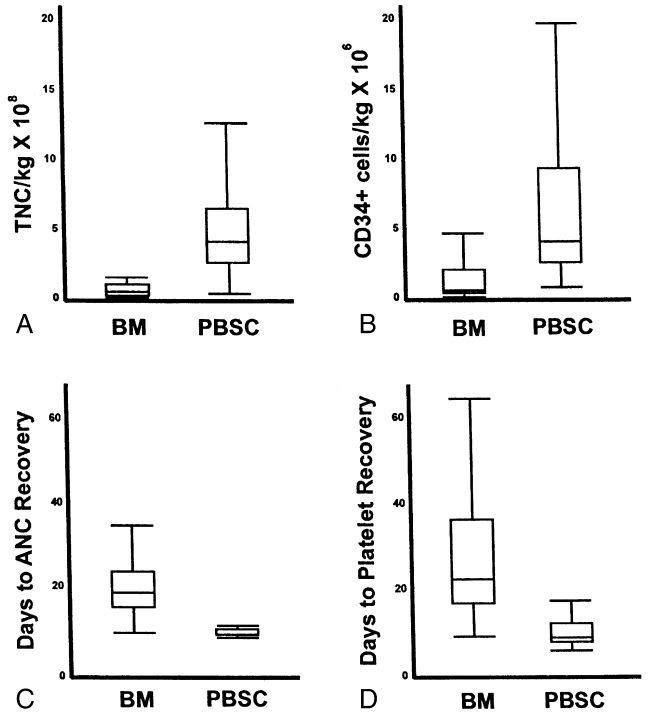

Figure 122-1 COMPARISON OF PERIPHERAL BLOOD STEM CELL (PBSC) PRODUCTS WITH BONE MARROW (BM). BM ($n = 187$) and PBSCs ($n = 104$) were collected from autologous donors at the Dana-Farber Cancer Institute and Brigham and Women's Hospital from 2000 through 2002. **A,** The total nucleated cell (TNC) content (TNC/kg recipient weight) was significantly higher in PBSC products (median, 4.2×10^8 nucleated cells/kg) than in BM products (0.5×10^8 nucleated cells/kg). **B,** The $CD34^+$ cell content of PBSC products was also significantly higher compared with BM (median, 4.3×10^6 $CD34^+$ cells/kg versus 0.5×10^6 $CD34^+$ cells/kg). **C,** Reconstitution of neutrophils (absolute neutrophil count [ANC] $>0.5 \times 10^9$/L) occurred more rapidly in recipients of PBSCs (median, 10 days) compared with BM (median, 18 days). **D,** Similarly, platelet recovery (platelet count $>20 \times 10^9$/L) was more rapid in PBSC recipients (median, 11 days versus 27 days for BM recipients). *(Courtesy G. Kao, Dana-Farber Cancer Institute, Boston, Mass.)*

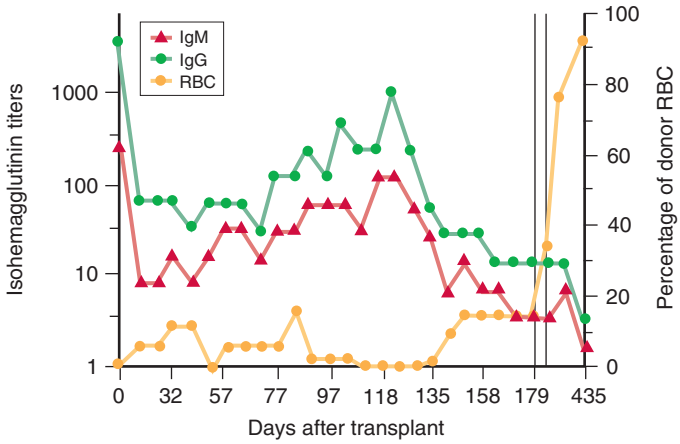

Figure 122-2 DELAYED RED BLOOD CELL (RBC) RECONSTITUTION IN THE RECIPIENT OF A MAJOR ABO-INCOMPATIBLE STEM CELL TRANSPLANT. The appearance of mature RBCs corresponded to declining antidonor isohemagglutinin titers. This patient remained RBC transfusion dependent for 12 months after transplantation. *Ig,* Immunoglobulin. *(From Maciej Zaucha J, Mielcarek M, Takatu A, et al: Engraftment of early erythroid progenitors is not delayed after non-myeloablative major ABO-incompatible hematopoietic stem cell transplantation.* Br J Haematol *119:740, 2002.)*

practices. The Food and Drug Administration (FDA) has driven the concept that all human cellular or tissue-derived therapies, regardless of source, need to fit into an established regulatory framework and must meet the same essential requirements for donor screening and good tissue practices. Two U.S. accrediting agencies, the American Association of Blood Banks (AABB) and the Foundation for the Accreditation of Cellular Therapy (FACT), have developed standards for collecting, testing, processing, and storing UCB samples, with the intent of ensuring the quality of UCB products provided.

ABO-INCOMPATIBLE HEMATOPOIETIC STEM CELL TRANSPLANTATION

In approximately 20% of allogeneic HSCT, ABO incompatibility exists between the donor and recipient.[8] ABO incompatibility is classified as major (the recipient has ABO antibody directed against donor RBCs), minor (the donor has ABO antibody directed against recipient RBCs), or both (major-minor). In most cases, the clinical impact of donor-recipient ABO incompatibility on HSCT is minimal. ABO incompatibility does not appear to affect overall patient survival, graft rejection, or GVHD. Nevertheless, clinically significant hemolytic complications resulting from ABO incompatibility occasionally do occur.

In major ABO-incompatible HSCT (e.g., group A donor → group O recipient), two types of hemolytic complications may be seen. Immediately on infusion, mature donor RBCs contained within the stem cell product may be destroyed by preformed ABO antibody in the recipient. The usual practice is to reduce the volume of RBCs contaminating major ABO-incompatible stem cell products to less than 10 mL. This manipulation effectively eliminates most immediate hemolytic reactions.

The second potential hemolytic complication of major ABO-incompatible HSCT is that recovery of the recipient's RBC counts may be delayed, in some cases dramatically (Fig. 122-2). This condition is a form of pure red cell aplasia (PRCA).[9] PRCA is characterized by peripheral blood reticulocytopenia and the absence of histologically detectable erythroid precursors in the bone marrow of the recipient. Peripheral-blood ABO antibody titers are characteristically elevated. Red cell transfusion dependence may last for several months after the recovery of platelets and granulocytes. Although red cell *reconstitution* is delayed in these cases, red cell *engraftment* is not. Using in vitro colony assays, the presence of early erythroid progenitors can be demonstrated in the bone marrow at the same time after transplantation as myeloid progenitors.[10] Early erythroid progenitors do not express ABO antigens and appear to survive normally in the bone marrow. On undergoing differentiation, the erythroid precursors begin expressing ABO antigens and are targeted by host ABO antibodies. It has been proposed that PRCA associated with major ABO-mismatched HSCT may be more likely to occur in the setting of nonmyeloablative SCT, because host hematopoiesis may be relatively preserved.[11] A higher PRCA rate in nonmyeloablative SCT has not been observed consistently, however, perhaps because of differences in treatment regimens. The optimal therapy for PRCA after major ABO-incompatible HSCT has not been defined. Various treatment modalities used with variable success have included plasma exchange, corticosteroids, rHuEPO, antithymocyte globulin, donor lymphocyte infusion, rituximab, and discontinuation of cyclosporine.

Minor ABO-incompatible HSCT (e.g., group O donor → group A recipient) has been associated with immediate hemolysis from passively transfused donor ABO antibody and with delayed hemolysis caused by ABO antibodies produced by mature donor lymphocytes contained in the graft. Minor ABO incompatibility does not affect overall rates of graft rejection, GVHD, or patient survival. Depletion of donor plasma in the graft generally eliminates the problem of

immediate hemolysis caused by passively transfused ABO antibody. The more serious potential problem is the passenger lymphocyte syndrome, in which mature donor lymphocytes engraft in the host and produce anti-A or anti-B antibodies that bind to and cause the destruction of circulating host RBCs (Fig. 122-3). This complication typically occurs 1 to 3 weeks after transplantation and is heralded by a positive direct antiglobulin test and a fall in hematocrit level. Rarely, hemolysis may be massive. Standard practice is to transfuse group O or donor group RBCs to dilute the recipient red cells and to monitor patients closely for clinical and laboratory evidence of hemolysis. Exchange transfusion has been performed in this setting but is usually unnecessary.

Less is known about ABO incompatibility with respect to UCB transplantation versus PBSC transplantation or BMT. Recent case series, however, suggest that PRCA and other isoagglutinin-mediated potential adverse consequences of ABO-incompatible stem cell transplantation are far less likely to occur with UCB than with the other stem cell sources. Tomonari et al,[12] for example, reported 0 cases of PRCA among 21 major and 18 major-minor ABO-mismatched UCB recipients. Zero of 29 recipients of minor ABO-incompatible UCB transplants developed immune hemolysis in their series. Similarly, Snell et al[13] reported that 0 of 14 minor ABO-incompatible UCB recipients developed immune hemolysis, compared with 14 of 25 contemporaneous patients who developed immune hemolysis after receiving a minor ABO-incompatible PBSC transplant.

The blood bank places specific RBC and plasma restrictions on patients undergoing ABO-incompatible HSCT (Table 122-1). RBCs are selected to be compatible with donor and recipient plasma, and plasma products are selected to be compatible with donor and recipient RBCs. These practices are begun on day 0 of HSCT or earlier if feasible. ABO antigens are widely expressed on endothelial tissues; HSCT recipients therefore may be considered ABO chimeras even after full RBC recovery.

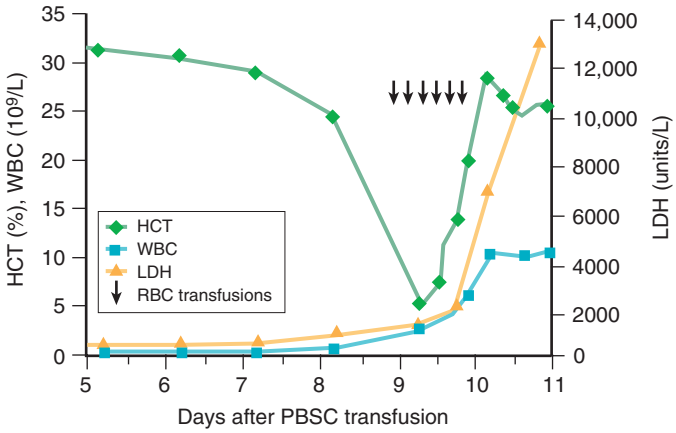

Figure 122-3 SEVERE HEMOLYSIS IN THE RECIPIENT OF A MINOR ABO-INCOMPATIBLE STEM CELL TRANSPLANT. Serologic testing revealed that donor-type anti-A isoagglutinins caused the hemolysis. *HCT,* Hematocrit; *LDH,* lactate dehydrogenase; *RBC,* red blood cell; *WBC,* white blood cell. *(From Bolan CD, Childs RW, Procter JL, et al: Massive immune haemolysis after allogeneic peripheral blood stem cell transplantation with minor ABO incompatibility.* Br J Haematol *112:787, 2001.)*

Table 122-1 Examples of Transfusion Restrictions After ABO-Incompatible Hematopoietic Stem Cell Transplantation

ABO Type			Transfusion Restriction	
Donor	*Recipient*	*Type of Mismatch*	*Red Blood Cell*	*Plasma*

A	O	Major	O	A or AB
O	B	Minor	O	B or AB
A	B	Major-minor	O	AB

PROPHYLACTIC PLATELET TRANSFUSIONS

Most platelet transfusions administered to cancer patients are given prophylactically rather than to control active bleeding. In the past, a platelet count of 20,000/mm^3 was generally used as a transfusion "trigger." Later studies have supported the concept that prophylactic platelet transfusions can safely be provided using even lower platelet thresholds, with associated inventory and cost savings. In an observational study of acute leukemia patients, Gmur et al[14] demonstrated that the platelet transfusion threshold could be set safely at 5000/mm^3 for patients without fever or bleeding, and at 10,000/mm^3 for patients with such signs. Platelet transfusion triggers of 10,000/mm^3 versus 20,000/mm^3 were compared directly in two randomized, prospective studies of patients with acute leukemia.[15,16] Both of these studies and a third nonrandomized, prospective study[17] demonstrated no increased risk for bleeding when a trigger of 10,000/mm^3 was used. All of these trials included provisions for transfusing thrombocytopenic patients at higher platelet counts if associated risk factors for bleeding (e.g., fever) were present. Relatively few studies have directly examined prophylactic platelet transfusion specifically in the setting of HSCT. Nevertheless, the 10,000/mm^3 trigger has been widely applied to the HSCT patient population, and it appears to be safe for patients lacking associated clinical factors (e.g., infection, GVHD). Frequently these clinical factors are more important determinants of bleeding risk than the platelet count alone.

The widespread use of a 10,000/mm^3 transfusion trigger is believed to have helped conserve the overall platelet supply. A potential complementary approach is one of optimizing the dose of prophylactic platelets transfused. A randomized controlled trial designed to empirically determine the optimal prophylactic platelet dose was reported by the Transfusion Medicine/Hemostasis Clinical Trials Network.[18] In this study, termed *PLADO* (PLAtelet DOsing), thrombocytopenic patients were randomized to receive either medium-dose (standard) (2.2×10^{11} platelets/m^2), low-dose (1.1×10^{11} platelets/m^2), or high-dose (4.4×10^{11} platelets/m^2) prophylactic platelets. The primary end point, World Health Organization grade 2 or higher bleeding, was observed in 71%, 69%, and 70% of the patients in the low-, medium-, and high-dose groups, respectively (i.e., there were no significant differences between the groups). Although low-dose platelets provided effective prophylaxis, patients in the low-dose group did require more platelet transfusions (median of five versus three for the medium-dose and high-dose group patients, $P < 0.001$). An alternative strategy, using therapeutic rather than prophylactic platelet transfusions, is currently under investigation.

ALLOIMMUNIZATION AND PLATELET REFRACTORINESS

Because HSCT patients typically receive large numbers of transfusions with cellular blood products, they are at risk for becoming alloimmunized to HLA antigens. Although graft failure associated with histocompatibility differences between donor and recipient is usually attributed to rejection by host T lymphocytes, host antibodies may also mediate graft failure by complement-mediated cytotoxicity or by antibody-dependent cell-mediated cytotoxicity. To prevent graft failure and platelet refractoriness, it is important to prevent HLA alloimmunization in patients who are possible candidates for HSCT. In particular, blood transfusions from the potential stem cell donor should be avoided because of the risk for sensitizing the patient to HLA and non-HLA antigens.

Platelet refractoriness may be defined as the failure to achieve an adequate platelet increment after two or more platelet transfusions (Table 122-2). A number of nonimmune factors have been linked to

Table 122-2 Causes of Platelet Refractoriness

Patient Factor	Clinical Effects	Blood Bank
Alloimmunization	Fever	ABO match
Bone marrow transplantation	Sepsis	Platelet storage time
Gender	Splenomegaly	Platelet cross-match
Circulating IVIG	Clinical bleeding	HLA match
Transfusion number	RBC use DIC Neutropenia

HLA, Human leukocyte antigen.

platelet refractoriness, including fever, sepsis, disseminated intravascular coagulation, drugs (e.g., amphotericin), bleeding, splenomegaly, hepatic venoocclusive disease, and GVHD. In a subset of cases, platelet refractoriness is caused by alloimmunization. Platelets express HLA class I antigens, relatively low levels of ABO antigens, and several platelet-specific antigens. All of these molecules are potential targets of an immune response. Antibodies directed against HLA molecules are responsible for most cases of immune-mediated platelet refractoriness. Notably, less than half of all platelet-refractory patients have demonstrable antiplatelet or anti-HLA antibodies. Platelet counts obtained at 10 minutes to 1 hour posttransfusion that repeatedly fail to demonstrate an adequate corrected count increment usually indicate an immune mechanism of platelet destruction.[19] If the 10-minute to 1-hour posttransfusion platelet count shows a reasonable increment, but the platelet count falls back to baseline by 18 to 24 hours, a nonimmune mechanism of refractoriness may be presumed. Demonstrating the presence of HLA antibodies in the recipient provides a second important line of evidence for immune refractoriness.

Although platelets express class I HLA antigens, platelets themselves are poor immunogens. Preclinical studies in rodent models suggested that white blood cells (WBCs) contaminating platelet products are the cells primarily responsible for stimulating an anti-HLA immune response in platelet transfusion recipients. It was hypothesized that removing WBCs from platelet products could prevent alloimmunization and platelet refractoriness. This was subsequently shown to be true in human studies. The definitive study was the multicenter prospective Trial to Reduce Alloimmunization to Platelets (TRAP study),[20] which compared alloimmunization rates in 530 newly diagnosed acute myeloid leukemia (AML) patients randomized to receive unmodified, pooled platelet concentrates (control); filtered, pooled platelet concentrates (F-PC); filtered single-donor apheresis platelets (F-AP); or ultraviolet B (UVB)–irradiated pooled platelet concentrates (UVB-PC). Anti-HLA antibodies were detected in 45% of controls, compared with 17% to 21% of patients receiving modified platelets. Thirteen percent of control group patients became platelet refractory, compared with only 3% in the F-PC group, 4% in the F-AP group, and 5% in the UVB-PC group.

Current filtration and apheresis technology can yield blood products with less than 10^6 residual leukocytes. It is standard practice to provide patients requiring long-term blood component support with leukoreduced products. Leukoreduction provides the additional benefit of reducing CMV risk in susceptible patients and of reducing the rates of febrile nonhemolytic transfusion reactions. The benefits in the HSCT patient population are clear; whether prestorage leukoreduced products need to be provided to all patients is controversial. Blood suppliers in many European countries and Canada have moved to providing exclusively prestorage leukoreduced products. Suppliers in the United States have made efforts to do the same, although universal prestorage leukoreduction is currently not mandated by the regulatory agencies (e.g., FDA, AABB) overseeing blood transfusion practices.

Once platelet refractoriness has been demonstrated, several strategies may help in obtaining therapeutic platelet increments in vivo. If refractoriness is nonimmune in nature (e.g., sepsis), the underlying cause must be treated. A trial of ABO-matched, fresh (1 to 2 days old) platelets may be helpful. In cases of immune-mediated refractoriness, a trial of HLA-matched platelets or crossmatched platelets may be indicated. Owing to the polymorphism of the HLA loci, it is often not possible to find perfect HLA-A and HLA -B locus matches, leading to the use of platelets mismatched at one or more loci (Table 122-3). Grade A (four antigens matched) or BU (three antigens matched/one antigen unknown) matched platelets provide the highest probability of a successful response.

CYTOMEGALOVIRUS INFECTION

CMV is a human herpesvirus (HHV-5) capable of infecting a variety of cell types, including mature WBCs and their progenitors. CMV causes significant morbidity and mortality in immunocompromised patients, including seronegative HSCT recipients. Allogeneic HSCT patients in particular are at risk for developing serious manifestations of CMV disease, which include pneumonitis, gastroenteritis, hepatitis, encephalitis, and retinitis. CMV disease is considerably less common in the autologous transplant setting. When a patient who is CMV seropositive at baseline undergoes HSCT, CMV disease occurs primarily as a result of reactivation of latent virus. In those cases in which the HSCT donor is seropositive and the recipient is seronegative, CMV transmission may occur by means of the stem cell product. When both donor and recipient are seronegative, CMV infection results primarily from the transfusion of infectious blood components.[21]

Serologic screening of blood products is currently the most effective means of reducing the risk for transfusion-transmitted CMV. The infrequent CMV infections still seen in part represent limitations of the serologic testing methodologies, such as donations made in the preseroconversion window period. Because the seroprevalence of CMV in various communities ranges from 40% to 80%, it is logistically difficult for blood banks to maintain an inventory of CMV-seronegative components. As an alternative to serologic screening, leukoreduction of blood components using filtration or other means has been used to render blood products "CMV safe." The AABB defines leukoreduced products as containing less than 5×10^6 WBCs. In 1995, Bowden et al[22] reported a large prospective study of 502 seronegative marrow transplant patients randomized to receive

seronegative or filtered blood products to test the hypothesis that these methods are equivalent in preventing CMV transmission. In the primary statistical analysis, there were no significant differences in the rates of CMV infection (1.3% versus 2.4%) or CMV disease (0% versus 2.4%) between the seronegative and filtered arms, respectively. The primary analysis excluded patients who seroconverted within the first 21 days of HSCT, based on the premise that they most likely would have been infected with CMV before transplantation. Complicating the interpretation of this study is that a secondary analysis of all patients seroconverting between days 0 and 100 showed a significantly worse outcome for patients in the filtered arm: 2.4% of patients in the filtered arm developed CMV disease, compared with 0% in the seronegative arm. Moreover, five of the six patients in the filtered arm who developed CMV disease progressed to fatal pneumonia. There were no deaths in the seronegative arm. Another confounding factor is that bedside filtration was used, which was subsequently shown to suffer from a relatively high rate of failure. Later methods would be expected to provide better and more consistent leukoreduction. Nevertheless, patients receiving leukoreduced blood showed a low level (2.4%) of CMV infection, which is in keeping with the historical figures of 1% to 4% CMV seroconversion with the use of CMV-seronegative components. The investigators conclude by stating: "We believe that the results of this study justify abandoning the maintenance of dual inventories of seronegative and unscreened blood products. The need to perform serologic screening of blood products of CMV could be eliminated altogether."

Given the previous considerations and the data associating filtered RBC units with an increased risk for CMV infection in HSCT patients, it remains unclear whether leukoreduced products are equivalent to seronegative products for the prevention of CMV transmission. It is certain that leukoreduction is extremely effective in decreasing CMV transmission, and the use of leukoreduced CMV-safe products as a substitute for seronegative products has become an accepted practice standard. Overall, although transfusion-transmitted CMV remains a problem in the HSCT population, the rates seen using seronegative or leukoreduced products are far lower than they have been in the past, in large part because of improvements in surveillance and preemptive therapy.

TRANSFUSION-ASSOCIATED GRAFT-VERSUS-HOST DISEASE

TA-GVHD is a devastating complication of blood transfusion primarily affecting immunocompromised patients, including patients undergoing allogeneic or autologous HSCT. The basic mechanism underlying TA-GVHD is that viable, immunocompetent lymphocytes in a blood product engraft and proliferate in the transfusion recipient. The donor lymphocytes attack host tissues, including skin, liver, intestine, and marrow. Signs and symptoms generally appear 7 to 10 days after transfusion. Patients typically present with fever, rash, elevated liver function test results, and nausea, vomiting, and diarrhea. Severe, refractory pancytopenia often develops as well, in most cases leading to the patient's death. The pancytopenia seen differentiates TA-GVHD from classic GVHD after HSCT. Whereas TA-GVHD involves immune rejection of host marrow cells, the marrow is spared in classic GVHD, because donor and recipient BM are selected to be HLA compatible. In most cases, TA-GVHD is fatal within 3 to 4 weeks of transfusion, with most patients dying from complications of marrow failure (i.e., bleeding or infection).

TA-GVHD occasionally occurs in completely immunocompetent patients. In these cases, the mechanism is a "one-way" HLA match, in which the transfusion recipient shares an HLA haplotype with a donor who is homozygous for that haplotype. The transfused lymphocytes are recognized as self by the host immune system and are not rejected. The recipient's cells, however, are seen as foreign by the infused lymphocytes, leading to a GVH response. Shared HLA haplotypes are more likely to occur among first-degree family members and in population groups with limited HLA heterogeneity. In the United States, the risk for transfusion of blood from HLA-homozygous donors to unrelated HLA-heterozygous patients is estimated to be approximately 1 in 7174. In Japan, a more genetically homogeneous population, the risk is much greater (1 in 874).[23] The incidence of TA-GVHD in the United States is clearly much lower than would be expected based on HLA considerations alone. Although underreporting may play a role, it is likely that other factors, including the use of blood that is stored for up to 6 weeks (with decreased leukocyte viability) and the rejection of HLA-homozygous cells based on minor transplantation antigens, also are factors.

There is no effective therapy for TA-GVHD. Fortunately, TA-GVHD is effectively prevented by γ-irradiation of blood products before transfusion. One case of TA-GVHD has been documented after irradiation with 1500 rad, and previous studies suggest that irradiation to 2000 rad is required to reduce mitogen-responsive lymphocytes by 5 to 6 logs compared with nonirradiated controls. Based on these observations, irradiated blood products are required to receive 2500 rad (25 Gy) to the central part of the container, with 1500 rad (15 Gy) as the minimum dose to any other point. Cellular blood products are required to be irradiated for the following situations: recipients identified to be at risk for TA-GVHD, donations made by blood relatives of the recipient, and donors selected to be HLA-matched with the recipient. At this time, it is recommended that only cellular blood products and fresh plasma be irradiated. TA-GVHD has not been reported to be caused by transfusion of plasma or cryoprecipitate that has been frozen and thawed.

SOLID ORGAN TRANSPLANTATION

Transfusion medicine is integral to the success of any solid organ transplantation program. The role of the transfusion medicine specialist and hematologist focuses on blood group compatibility, histocompatibility, transfusion and coagulation support, and adjunctive treatment of humoral rejection. Improved surgical technique and advances in prevention of allograft rejection have led to tremendous growth in solid organ transplantation during the past decade. During 2002, for example, 25,700 solid organ transplantations were performed, including more than 14,000 kidney, 5000 liver, 2000 heart, and 1000 lung transplantations in the United States. The annual report of the United Network for Organ Sharing (UNOS) is available on the Internet (http://optn.transplant.hrsa.gov/data/annualreport.asp). The availability of multiple drugs to prevent organ rejection, including prednisone, cyclosporine (Sandimmune, Neoral, SangCya), tacrolimus (Prograf, FK506), mycophenolate mofetil (CellCept), daclizumab (Zenapax), antithymocyte globulins (Atgam, Thymoglobulin, murine monoclonal antibodies (Orthoclone OKT3) and rapamycin (Rapamune), has extended graft and patient survival. Designed to suppress T-cell activation and cytokine release, these drugs are not cytotoxic agents and lack direct marrow toxicity.

IMMUNOHEMATOLOGY AND SOLID ORGAN TRANSPLANTATION

Renal Transplantation

Pretransplantation Blood Transfusion

Numerous studies documented that pretransplantation blood transfusions promoted prolonged renal allograft survival. As a result, deliberate use of random donor transfusions before cadaver donor renal transplantation and donor-specific transfusions before living-related donor transplants became widespread. A proportion of deliberately transfused patients became HLA alloimmunized, however, and the resulting HLA incompatibility eliminated them as candidates for transplantation. The introduction of cyclosporine in the 1980s led to improved graft survival, and the benefit of pretransplantation transfusions became more difficult to document. As a result, the practice of pretransplant transfusion was abandoned.

ABO Compatibility

ABO compatibility between donor antigens and recipient antibodies is critical for successful renal transplantation. ABH antigens are richly expressed on vascular endothelial cells and renal cells and are excreted in the urine. As a result, ABO-incompatible grafts are at high risk for humoral rejection, and transplantation against ABO barriers has traditionally been contraindicated. Because group O recipients are restricted to group O donors, several experimental protocols have investigated the use of group A_2 donors (who express group A antigens at approximately one-fourth the strength of group A_1 individuals) for group O or group B recipients with low-titer anti-A antibodies.[24] Protocols aimed at allowing renal transplantation across the ABO barrier typically involve pretransplant plasmapheresis or immunoadsorption to remove anti-ABO antibodies, in combination with immunosuppressive agents and careful monitoring of antibody titers. Short-term results with such protocols have in some cases been encouraging. In some cases, high titers of anti-ABO antibody can continue to circulate in the recipient—but without corresponding damage to the antigen-positive transplanted organ. This phenomenon, termed *accommodation,* is not well understood.

HLA Compatibility

The importance of serologic HLA compatibility between donor antigens and recipient antibodies is well established for renal transplantation. Recipients who express warm-reactive antibodies to HLA class I antigens of the donor are at risk for hyperacute rejection characterized by complement activation, intravascular coagulation in the graft, organ ischemia, and necrosis that may occur within minutes of establishing blood flow to the graft. Several techniques are used for HLA crossmatching, and there is controversy regarding which method has the highest predictive value. Standards of the American Society for Histocompatibility and Immunogenetics require that the final crossmatch employ a technique with greater sensitivity than the basic microlymphocytotoxicity test. Such techniques may use longer incubation times, more wash steps, an antiglobulin reagent, B-cell targets, dithiothreitol, or flow cytometry.

Recognition of the importance of HLA-serologic compatibility led to the practice of monthly HLA antibody screening of serum from HLA-sensitized patients awaiting kidney transplants. Antibody specificities that are identified are recorded, and the corresponding antigens avoided when allocating suitable kidney allografts. Some programs also consider compatibility results using archived sera when allocating allografts to recipients who are known to be HLA sensitized. Analysis of recipient HLA specificities has revealed that identification of antibodies directed against common "public antigens" may be more clinically meaningful than antibodies to private HLA antigens. Understanding the exact value of HLA matching for long-term graft acceptance is complicated by the power of immunosuppressive medications, the polymorphism of the HLA system, variable response to different loci within the major histocompatibility complex, and the confounding effects from minor histocompatibility antigens. Studies of the precise value of matching have yielded conflicting results; nevertheless, consideration of the extent of match remains a high priority in organ allocation. Deoxyribonucleic acid (DNA)–based HLA typing continues to advance understanding of the role for HLA matching in renal transplantation.

Routine practice does not require HLA matching of donor and recipient when allocating cadaver kidneys. However, retrospective studies of graft survival have suggested that certain HLA mismatches are associated with a higher incidence of rejection, and large retrospective analyses have provided evidence that greater degrees of HLA matching between the donor and recipient result in longer graft survival. Although not all have agreed that matching improves outcomes, the potential benefits have prompted organ banks to allocate cadaver organs based on the degree of HLA match rather than simply on the results of HLA-compatibility testing. However, matching cadaver organs to distant recipients may carry the disadvantage of prolonged cold-ischemia time. As a result, allocation based on HLA matching combined with limitation of cold-ischemia time is used. Despite the beneficial effects of HLA matching, matched cadaver transplants do not survive as well as matched living-related transplants. The difference may reflect not only injury to the graft during preservation but also the influence of histocompatibility mismatches not recognized by existing HLA-typing techniques.

Liver Transplantation

ABO Compatibility

Ordinarily the donor liver must be ABO compatible with the recipient. Transplantation of ABO-incompatible livers has occurred by error or under urgent circumstances, with limited success. ABO-incompatible liver transplants may occur more frequently in pediatric cases when a compatible donor organ is unavailable and recipient blood group alloantibodies are poorly developed. Data from the UNOS scientific registry found that ABO mismatch was among the strongest independent predictors of adverse outcome after emergency liver transplantation. The immune response to ABO-incompatible grafts is consistent with a pattern of hyperacute rejection. No standards exist regarding transfusion support for ABO-incompatible grafts, but the use of RBCs and fresh frozen plasma (FFP) compatible with both donor and recipient would seem desirable.

Hemolytic Antibodies of Donor Origin

Passenger lymphocytes that accompany a graft may continue to secrete antibodies directed against blood group antigens during the early postoperative period. If the recipient's native red cells or transfused red cells express the matching antigen, a Coombs-positive hemolytic anemia may appear approximately 1 week after transplant.[25] Although the direct antiglobulin test may only be weakly reactive, rather brisk hemolysis typical of complement fixing ABO antibodies can occur. Acute renal failure from intravascular hemolysis in this setting is rare but has been reported.

Approximately 30% of patients transplanted with ABO-compatible but nonidentical livers have been reported to develop postoperative hemolysis mediated by anti-ABO antibodies produced by passenger lymphocytes. Hemolysis has also been reported to result from non-ABO blood group antigens but is most commonly seen when the donor is group O and the recipient is group A_1. Posttransplant hemolysis has been reported after all types of major solid organ transplants, including liver, kidney, heart-lung, spleen, and pancreas. It is most common after liver transplantation, probably by virtue of the greater number of passenger lymphocytes that accompany this large organ. This phenomenon is uncommon after kidney transplantation because of UNOS policies that reserve group O donors for group O recipients. The diagnosis is confirmed by testing an eluate made from the patient's red cells against non–group O target cells—a test not routinely done by the blood bank in the evaluation of a positive direct antiglobulin test. Treatment consists of transfusion with cells compatible with donor and recipient antibodies. Red cell exchange is usually not required, and the condition is generally self-limited because donor lymphocytes are deleted posttransplant.

Alloantibodies to Red Cell Antigens

Patients with clinically significant alloantibodies directed against red cell antigens outside the ABO system pose a unique problem in the setting of the massive transfusion requirements that unpredictably accompany liver transplantation. Depending on the availability of antigen-negative donor units, one strategy is to begin surgery with antigen negative–compatible red cells and then allow transfusion to

"wash out" recipient alloantibody before switching to antigen-positive red cells. Approximately one blood volume of antigen-negative units can be reserved for the end of the case to reconstitute the patient with compatible blood for the postoperative period. Antibody washout can be roughly predicted from the presurgical antibody titer as measured by twofold serial dilution. Each blood volume of transfusion reduces the titer by one dilution. For example, an antibody that reacts at 1:16 titer requires roughly four blood volumes of transfusion to wash out.

Heart and Lung Transplantation

Cardiac transplantation has become an established therapy for life-threatening cardiac dysfunction, including coronary disease, cardiomyopathy, and congenital cardiac defects. One-year patient survival rates of approximately 85% and 5-year survival rates of 70% have been achieved through the use of effective immunosuppressive regimens, improved recipient selection criteria, the use of heart-assist devices to bridge the waiting time between diagnosis and transplantation, the development of percutaneous endomyocardial biopsy for improved detection of early rejection episodes, and more effective management of postoperative infectious complications. As a result of these improvements, research has shifted from short-term problems such as acute rejection to those factors influencing long-term morbidity-free survival.

Cadaver lung transplants and living-related partial lung transplants have been used in the treatment of a variety of end-stage pulmonary diseases, including cystic fibrosis, emphysema, and α_1-antitrypsin deficiency. A variety of techniques have been developed to prevent rejection of the bronchial anastomosis between donor and recipient. Combined heart-lung transplants are infrequent and are used in the treatment of congenital heart disease with Eisenmenger syndrome or primary pulmonary hypertension.

ABO Compatibility

Because ABO antigens are present on cardiac endothelial tissue, ABO compatibility of donor and recipient is a prerequisite for heart transplantation. ABO is a major determinant of waiting time for heart and lung transplant recipients, with group O recipients consistently requiring longer waiting times. As with other solid organ transplants, ABO-compatible but ABO-nonidentical allografts are used. However, ABO-identical transplants may have a better overall survival than ABO-compatible but ABO-nonidentical grafts. ABO-incompatible heart transplants are absolutely contraindicated in adults because of the risk for hyperacute rejection. However, many successful ABO-incompatible heart transplants have been performed in infants.[26] The infant immune system does not produce T cell–independent antibodies, and early ABO-incompatible heart transplantation produces tolerance in the recipient to donor blood group A or B antigens. The primary mechanism underlying this tolerance appears to be specific elimination of donor-reactive B lymphocytes. Thus a type O infant who receives a type A heart transplant will typically have normal levels of circulating anti-B antibody, but not the usually expected anti-A antibody later in life.

HLA Compatibility

The clinical significance of HLA-antibody testing in cardiac and lung transplantation remains controversial, and surveyed practices show a lack of consensus. Recipients with HLA antibodies to donor antigens do not experience hyperacute rejection, and some studies have reported no adverse outcomes despite incompatible crossmatches at the time of transplantation. However, most studies have found that patients with HLA antibodies, detected by a pretransplantation HLA crossmatch or by a highly panel reactive antibody (PRA), have a higher frequency of rejection episodes in the first months after transplantation. Whether this reflects a direct effect of HLA antibodies or represents a marker of recipient cellular immune responsiveness is not resolved. For example, in a review of 500 cardiac transplants at the Cleveland Clinic, sensitized patients (PRA >10%) had a 1-year graft survival of 76% compared with 89% for nonsensitized patients ($P = 0.02$).[27] As with renal transplants, some studies have suggested that antibodies to class I HLA antigens or antigens specific to the donor are more important predictors for early rejection episodes. Other studies have not found HLA antibodies to play a critical role in graft rejection.

Xenoantibodies

Naturally occurring xenoantibodies in humans represent a major immunologic barrier to xenotransplants. Similar to ABO antibodies, xenoantibodies are directed against sugar epitopes, including α-galactose found on the cells of all mammals other than humans and Old World monkeys. Antibodies to α-galactose fix complement avidly and produce a potent hyperacute rejection. As a result, strategies to overcome this immune barrier have been directed against the level of antibody and against prevention of complement activation.

TRANSFUSION MEDICINE SUPPORT FOR SOLID ORGAN TRANSPLANTATION

Specialized Blood Components

Cytomegalovirus–Reduced Risk Blood

The implications of CMV infection are different in solid organ transplant recipients compared with bone marrow transplant recipients. After solid organ transplantation, the recipient's immune system is not chimeric, and immunosuppression is less extensive than that required for allogeneic marrow transplantation. As a result, solid organ recipients appear to have better immunity against infections such as CMV, which cause less postoperative morbidity.

Most serious CMV infections result from primary transmission from the donor allograft rather than from blood transfusion. CMV-seronegative recipients of CMV-seropositive allografts are therefore at greatest risk for posttransplantation infection regardless of blood transfusion therapies. When the recipient is CMV seropositive, reactivation infection is more common than transfusion-transmitted disease. Second-strain infection can occur from the allograft but has not been reported as a result of transfusion. This may result from the fact that the allograft is retained whereas blood donor leukocytes are largely apoptotic and cleared shortly after transfusion. When the organ donor or the recipient is CMV positive, the use of CMV-negative blood components should be considered investigational.

However, when both donor and recipient are CMV negative, CMV–reduced risk blood is indicated for lung transplantation. CMV–reduced risk blood is defined as blood from CMV-seronegative donors or leukoreduced blood—either of which can effectively prevent CMV transmission by transfusion. CMV–reduced risk blood is not generally used for adult liver transplant cases because of the large number of products required. CMV–reduced risk blood products are not a strict requirement among most solid organ recipients. For example, Preiksaitis et al[28] reported the incidence of postoperative CMV among CMV-seronegative recipients who were supported with CMV-untested and nonleukoreduced blood components. Although postoperative CMV was very common (131 [85%] of 154) when the organ allograft was CMV seropositive, CMV syndromes were at near background levels (3 [2.4%] of 127) when organ donor and recipient were CMV seronegative despite the use of blood components that were not CMV–reduced risk. Among the different categories of transplantation, the incidence of postoperative transfusion-associated CMV was 0 of 57 (0%, renal), 0 of 29 (0%, heart), 2 of 20 (10%,

liver), and 1 of 6 (16.7%, lung).[28] Current interest has centered on the use of PCR for the early detection of CMV infection as a guide to the preemptive use of ganciclovir.

γ-Irradiated Blood Components

Patients undergoing solid organ transplantation are not known to be at increased risk for TA-GVHD. As a result, γ-irradiated cellular blood components are not currently required for solid organ transplant recipients preoperatively or postoperatively. Because γ-irradiation results in dramatic elevation of plasma potassium levels in stored red cells, irradiated and stored red cells may increase the risk for hyperkalemic cardiac arrest at the time of massive transfusion.

Massive Transfusion During Liver Transplantation

Orthotopic liver transplantation (OLT) has become the treatment of choice for life-threatening end-stage hepatic failure. Successful OLT requires a close working relationship between the surgical team, anesthesia services, and blood services because the operation sometimes requires spectacular quantities of blood support. Improved surgical technique, use of venovenous bypass for those cases in which the vena cava is interrupted, argon laser–directed electrocoagulation, and better preservative solutions for storing the donor liver ex vivo have contributed to decreased transfusion requirements during surgery. One-year and 5-year patient survival rates are approximately 85% and 75%, respectively.

Causes of Bleeding

Intraoperative transfusion requirements for OLT cannot be predicted on the basis of preoperative coagulation screening. Rather, the presence of severe portal hypertension, previous right upper quadrant surgery, vascular abnormalities of the portal vein, poor left ventricular function, pulmonary hypertension, poor nutritional state, or comorbid diseases are the most important predictors of massive transfusion and decreased survival. Prior transjugular intrahepatic portosystemic stent-shunt does not appear to adversely affect surgical outcomes during OLT.

OLT requires a difficult right upper quadrant dissection of the recipient hepatic bed, which can be complicated by severe portal hypertension, friable collateral vessels, adhesions from prior procedures, or inflammation from the patient's underlying disease. Removal of the liver requires isolating the blood supply of the organ and clamping and cutting the portal vein, hepatic artery, common bile duct, and the hepatic vein or the inferior vena cava above and below the liver. The period after the recipient hepatectomy and before reestablishing blood flow to the new graft is referred to as the *anhepatic phase of surgery* and is the period of greatest risk.

Patients who require OLT usually have multiple hemostatic abnormalities associated with acute or chronic liver failure. Decreased coagulation factors, splenomegaly with thrombocytopenia, dysfibrinogenemia, and chronic fibrinolysis with elevated fibrin split products may all be present in varying combinations. Some patients develop a profound intraoperative fibrinolysis. Tissue plasminogen activator (tPA)—presumably released from recipient blood vessels or from the vessels of the graft in response to shock, acidosis, pharmacologic pressors, ischemia, or preservation injury—circulates in high concentration. Normally cleared by the liver, tPA released during and immediately after the anhepatic phase of surgery is not cleared from the bloodstream. As a result, tPA activity can reach 10 to 100 times normal levels, and a pathologic systemic lytic state ensues. A sudden decrease in all coagulation factors occurs with particularly marked declines in fibrinogen and factor VIII. Proteolysis of von Willebrand factor may also occur. Less severe cases may not demonstrate systemic lysis but may lyse clot at sites of previous hemostasis. As the liver allograft begins to function, tPA is rapidly cleared and fibrinolysis decreases.

Transfusion Support During Liver Transplantation Surgery

A rapid transfusion device designed to deliver large volumes of blood components in a rapid fashion is essential for OLT. These devices consist of a sterile holding reservoir, high-capacity blood filter, roller pump, in-line blood warmer, and air detection device. Blood is pumped through large-bore catheters placed in the antecubital or central veins. Intraoperative blood recovery devices are a useful adjunct to blood support during OLT, particularly in cases requiring massive transfusion. Blood suctioned from the operative field is anticoagulated with citrate and collected in a sterile holding reservoir. The shed blood is then centrifuged, the supernatant discarded, and the residual packed red cells washed with saline. The saline-suspended packed red cells may then be pumped to the rapid transfusion device or transferred to a plastic blood collection bag for later reinfusion.

OLT demands careful but aggressive component therapy guided by the clinical course and the results of intraoperative coagulation monitoring. Serial intraoperative hematocrit and coagulation monitoring using a limited number of tests with rapid turnaround time provides valuable information for rational blood component management. Some OLT centers monitor coagulation using thromboelastography—a method that measures whole blood coagulation by impedance to an oscillating cylinder. Other programs use traditional measurements such as the prothrombin time, fibrinogen concentration, and platelet count. Either method of monitoring is valuable, provided that testing is done serially, results are reported rapidly, changes are correlated in the operating room with the clinical picture, and abnormalities are interpreted by someone with experience in the coagulopathy of OLT.

Red cell support must be given in consideration of the competing needs of other patients. Probably as a consequence of postoperative immunosuppression, Rh-negative individuals transfused with Rh-positive blood at the time of transplantation are not likely to make anti-D. Nevertheless, Rh-negative women of childbearing age without anti-D are initially supported in many programs with a reasonable number of D-negative units and then switched to D-positive cells should more blood be needed. In some programs, Rh-negative males and females who are not of childbearing potential are treated from the outset with Rh-positive blood. Because many OLT patients are massively transfused, delayed hemolytic transfusion reactions in the postoperative period if directed against high-frequency antigens can result in dramatic hemolysis.

The use of FFP, platelet concentrates, and cryoprecipitate is guided by the clinical course and by the results of intraoperative monitoring. Although care must be given to prevent dilutional coagulopathy, it is not necessary to mix equal ratios of red cells and FFP or platelet concentrates. Reasonable goals of component therapy in the absence of fibrinolysis or other complications include an international normalized ratio (INR) of less than 2 or 2.5, a platelet count higher than 50,000 to 100,000/μL, and a fibrinogen concentration more than 100 mg/dL. Antifibrinolytic agents are indicated during or shortly after the anhepatic phase of surgery in those patients who demonstrate a systemic lytic state. A loading dose and continuous infusion of ε-aminocaproic acid, tranexamic acid, or aprotinin has been used with success. Hourly bolus doses have also been used. Tranexamic acid or aprotinin each reduced operative blood loss during liver transplantation when studied in randomized, prospective, placebo-controlled trials. Because the routine use of antifibrinolytics may result in thrombotic complications in some patients, our program uses antifibrinolytics for those patients who show evidence of fibrinolysis. Recombinant activated factor VII has been used to promote hemostasis during liver transplantation. Randomized controlled trials, however, have failed to demonstrate a favorable effect on blood loss.[29,30] For all patients, local hemostasis provided by meticulous and advanced surgical skill remains critically important.

Metabolic Complications of Massive Transfusion During Liver Transplantation Surgery

Patients undergoing massive transfusion during OLT are susceptible to all the major complications of massive transfusion, including hypothermia, dilutional coagulopathy, electrolyte imbalance, pulmonary dysfunction, and transfusion-transmitted infections. OLT patients are uniquely at risk for life-threatening hypocalcemia as a result of citrate toxicity. Magnesium is also chelated by citrate, and low magnesium concentrations may accompany massive transfusion during OLT surgery. Because the liver is the main organ for citrate metabolism and because OLT patients can receive very rapid infusions of large volumes of FFP that is rich in Na_3-citrate, the quantity of citrate infused per kilogram body weight per minute can quickly exceed the rate of citrate removal. Citrate toxicity is more pronounced if concomitant renal failure is present because the kidney is the major site of citrate excretion. The principal effects of citrate toxicity are cardiovascular. An initial blunted response of cardiac output to left-ventricular volume loading is followed by hypotension resulting from poor cardiac output and decreased systemic vascular resistance. If misinterpreted as hypotension due to hypovolemia, a more rapid transfusion of citrate-rich blood components will worsen cardiac output. Citrate toxicity is aggravated by hypothermia and hyperkalemia. Because a widened QTc interval on the electrocardiogram has low specificity and poor predictive value, intraoperative monitoring of the ionized calcium level is essential during OLT. Untreated severe depression of the ionized calcium or magnesium results in bizarre electrocardiographic disturbances and fatal arrhythmias.

Plasmapheresis and Photopheresis

The indications for plasmapheresis in transplantation patients remain poorly defined and not established by controlled clinical trials. Preoperative plasmapheresis or blood exchange is able to lower titers of ABO antibodies, especially those of the immunoglobulin M (IgM) class. Plasmapheresis is less effective at reducing titers of HLA antibodies, which are largely IgG in nature. Plasmapheresis has been reported to successfully treat some patients with postoperative HLA-mediated humoral rejection of renal allografts. Photopheresis refers to a treatment in which blood passes along an extracorporeal circuit and is exposed to a photoactive chemical (psoralen) plus ultraviolet light. Used initially in the treatment of Sézary syndrome, photopheresis has been applied to the treatment of solid organ transplant rejection unresponsive to standard therapy. Uncontrolled studies have reported success in cardiac, renal, lung, and liver transplants.

CHAPTER 123

PEDIATRIC TRANSFUSION MEDICINE

Cassandra Josephson and Steven R. Sloan

An essential element of treating various neonatal and pediatric disorders is transfusion of blood components. In order to provide excellent patient care for children it is paramount that clinicians have specific knowledge about blood-bank testing, blood-product components, specific transfusion indications, and potential adverse events.

PEDIATRIC BLOOD BANKING

Blood and Blood Components

Several different blood components, including whole blood, reconstituted whole blood, red blood cells (RBCs), platelets, plasma, and cryoprecipitated antihemophilic factor may be available from a blood bank for transfusion. The availability of specific component types varies between blood suppliers.

- Whole blood is infrequently used and may not be available from a particular blood bank or blood supplier, but it may be available on request and is used by some pediatric cardiac surgery services. Whole blood contains all RBCs, plasma, platelets, and an anticoagulant preservative solution containing citrate, phosphate, dextrose, and possibly adenine.
- RBC units mostly contain RBCs but also contain some plasma and a preservative solution. Most RBC units contain an additive preservative solution that includes some combination of adenine, dextrose, and mannitol. Additive solutions are safe for relatively small (≤20 mL/kg) transfusions. There are concerns over the safety of these additives given in large transfusions to neonates, and their safety in this setting has never been proven in a randomized clinical trial. In view of this concern, some blood banks provide nonadditive RBC units or wash additive units intended for large transfusions to neonates. Because many blood centers provide only additive RBC units and washing an RBC unit takes approximately 1 hour, blood banks have been unable to supply RBC units without additives in many situations. Thus many institutions now have significant experience transfusing large volumes of additive RBC units to neonates and have not noticed any problems.
- Two types of platelet units are available in the United States, although any one blood bank or hospital may stock only one of these types. These two types, whole blood–derived platelets (platelets) and platelets collected by apheresis (pheresis platelets), differ in their size. A platelet unit contains approximately 5.5 to 10×10^{10} platelets in about 50 mL, whereas a pheresis platelet unit contains at least 3×10^{11} platelets in about 200 mL. It is often easier to use platelet units for small children because pheresis platelets usually need to be prepared as aliquots to provide the correct dose. However, many blood centers exclusively provide only one type of platelet component.
- Plasma is traditionally stored as fresh frozen plasma (FFP) and contains all of the clotting factors and plasma proteins. Although some plasma components are not frozen quickly enough or are thawed for too long before transfusion to be called FFP in the United States, these components still contain all the necessary clotting factors.
- Cryoprecipitate is prepared from plasma and contains high concentrations of fibrinogen.

Because pediatric patients require smaller doses of blood components, they often require only a portion of a component.

- RBCs are stored refrigerated and hence can be prepared in aliquots as needed if the blood bank has the necessary equipment. Alternatively, the blood center can collect RBC units into a collection system in which additional bags are attached for dispensing aliquots. Whole blood is also stored refrigerated, but its use is very limited and it is almost never prepared in aliquots.
- Platelets and pheresis platelets are stored at room temperature under constant agitation and can be prepared in aliquots when needed in the blood bank if the blood bank has the necessary equipment and supplies. However, 1 unit of whole blood–derived platelets does not contain many doses, even for infants, and most blood banks do not find it worthwhile to prepare a unit of platelets in aliquots.
- Plasma is stored frozen, and preparing as aliquots after thawing is not practical or helpful because the plasma remaining after preparing an aliquot is not likely to be used. However, many blood centers will prepare plasma aliquots before freezing.
- Because even small infants rarely require less than 1 unit of cryoprecipitate, this component is rarely prepared in aliquots.

Directed Donations

Families often prefer to donate blood for their children using a process known as directed donations, and some blood banks permit this. If this is done without medical reason, it offers no benefit and there may be increased risks. Although directed donors need to go through the same screening and infectious disease–testing process as all allogeneic blood donors, some studies suggest that directed donors have a slightly higher risk for infectious disease transmission.

In addition, directed donors may be a poor choice for immunologic reasons. For example, if a neonate has alloimmune thrombocytopenia or anemia, the pathologic antibody is a passively acquired maternal antibody directed against inherited paternal antigens. In this case, blood donated by the father would be recognized by the antibody in the baby's circulation and cleared just as the neonate's own platelets are cleared. Another example in which immune concerns make directed donors a poor choice involves transplants. Some patients may require a future tissue or bone marrow transplant, and blood relatives often serve as the best donors for such transplants. However, prior transfusions from relatives may sensitize the patient's immune system to antigens present on the tissues of blood relatives, complicating those potential tissue or bone marrow transplants.

TECHNICAL CONSIDERATIONS/MECHANICAL DEVICES

The small size of pediatric patients necessitates smaller transfusions administered at slower rates. As a result, the transfusion process is subject to the introduction of multiple steps. As mentioned earlier, aliquots of components often need to be prepared. This can be performed with the use of blood collected into collection bags interconnected with sterile tubes. Alternatively, additional containers can be

attached to a standard blood component by using a sterile docking device, which produces a sterile weld between the two separate tubing sets. The details of when and where such preparation of aliquots occurs depend on the blood collection sets, the blood component, and the equipment and procedures available at the blood center and hospital blood bank.

Blood components must be filtered to remove microaggregates before transfusion. For an adult patient, this is normally accomplished by transfusing the component through a filter contained within the blood administration set. Although these standard blood administration sets are acceptable for all transfusions, they are not ideal for transfusing small patients because 20 to 40 mL of the component is lost in the dead space of the administration set. Pediatric microaggregate filters with much smaller dead space are available, and these are often used in the blood bank to filter an aliquot before transfusion.

Another issue concerns the standard transfusion rate for nonbleeding patients. The transfusion rate is generally no more than 5 mL/kg/hr. For infants, this corresponds to a lower rate than can be regulated by most standard infusion pumps. Hence such a transfusion is usually performed with the use of a syringe pump, and the blood component aliquot must be transferred to a syringe for the transfusion. Although various procedures can be used for this transfer, one of the simplest and safest is one in which the blood bank transfers an aliquot from the original unit through a pediatric microaggregate filter directly into a syringe. The blood bank dispenses the syringe, and the clinical staff administers the transfusion directly from the syringe and does not need to filter the component.

TRANSFUSION MEDICINE: GENERAL INDICATIONS AND DOSING

Indications for RBC Transfusion in Neonates, Children, and Adolescents

Neonates Less Than 4 Months Old

RBC transfusions are more commonly administered to hospitalized neonates than any other patient age-group, and RBCs are the component most often transfused in this population. When approximately 10% of the neonate's blood volume has been lost, RBC transfusion should be considered. Symptomatic anemia is the major indication for simple transfusion. When the venous hemoglobin is less than 13 g/dL in the first 24 hours of life, an RBC transfusion should be considered. A transfusion dose of 10-15 mL/kg of RBCs should yield an increase in the neonate of 3 g/dL of hemoglobin after transfusion. Two recent randomized clinical trials in premature infants examining restrictive versus liberal RBC transfusion practices have not resolved the controversy of when RBC transfusion is indicated in the neonatal intensive care unit patient.[1,2] Therefore most guidelines, several published over the past 15 to 20 years, continue to be based on experience rather than evidence-based medicine (Table 123-1).

Older Infants, Children, and Adolescents

RBC transfusion indications for infants older than 4 months and for young children are similar to adults. However, there are several noteworthy differences between children and adults: total blood volume, ability to tolerate blood loss, and age-specific hemoglobin levels (Table 123-2). In infants, RBC transfusions are primarily given for surgical losses, anemia of chronic diseases, and malignancies. Infants inherently have lower hemoglobin levels than adults. Consequently, infants remain asymptomatic at lower hemoglobin concentrations, especially if the anemia occurs gradually. Even with these physiologic differences, general transfusion-trigger guidelines for pediatric intensive care unit patients are similar to those for adults, with a transfusion trigger of 7 g/dL of hemoglobin for hemodynamically stable patients being shown to be safe for these patients.[3] This threshold also has been found to be safe for hematopoietic progenitor cell (HPC) transplant patients.[4] Dosing of RBCs is the same as for infants less than 4 months of age, 10 to 15 mL/kg despite the fact that more concentrated RBC units are often used for infants less than 4 months old.

Table 123-1 Guidelines for Transfusion of Red Blood Cells in Infants Less Than 4 Months of Age

1. Hematocrit <20% with low reticulocyte count and symptomatic anemia (tachycardia, tachypnea, poor feeding)
2. Hematocrit <30% and
 a. On <35% oxygen hood, or
 b. On oxygen by nasal cannula, or
 c. On continuous positive airway pressure and/or intermittent mandatory ventilation on mechanical ventilation with mean airway pressure <6 cm of water, or
 d. With significant tachycardia or tachypnea (heart rate >180 beats per minute for 24 hours or respiratory rate >80 breaths per minute for 24 hours)
 e. With significant apnea or bradycardia (more than six episodes in 12 hours or two episodes in 24 hours requiring bag and mask ventilation while receiving therapeutic doses of methylxanthines), or
 f. With slow weight gain (<10 g/day observed over 4 days while receiving >100 kcal/kg/day)
3. Hematocrit <35% and
 a. On >35% oxygen hood, or
 b. On continuous positive airway pressure/intermittent mandatory ventilation with mean airway pressure >6-8 cm of water
4. Hematocrit <45% and
 a. On extracorporeal membrane oxygenation (ECMO), or
 b. With congenital cyanotic heart disease

RBC, Red blood cell.

Table 123-2 Guidelines for Transfusion of Red Blood Cells in Patients More Than 4 Months of Age

1. Emergency surgical procedure in patient with significant postoperative anemia
2. Preoperative anemia when other corrective therapy is not available
3. Intraoperative blood loss ≥15% total blood volume
4. Hematocrit <21%-24%
 a. In perioperative period, with signs and symptoms of anemia
 b. While on chemotherapy/radiotherapy
 c. Chronic congenital or acquired symptomatic anemia
5. Hematocrit <21%, hemodynamically stable patients >3 days old in the pediatric intensive care unit
6. Acute blood loss with hypovolemia not responsive to other therapy
7. Hematocrit <40% and
 a. With severe pulmonary disease
 b. On ECMO
8. Sickle cell disease and
 a. Cerebrovascular accident
 b. Acute chest syndrome
 c. Splenic sequestration
 d. Aplastic crisis
 e. Recurrent priapism
 f. Preoperatively when general anesthesia is planned (target hemoglobin 10 mg/dL)
9. Chronic transfusion programs for disorders of RBC production (e.g., β-thalassemia major and Diamond-Blackfan syndrome unresponsive to therapy)

Platelets

Platelet transfusion support in neonates less than 4 months of age, those older than 4 months, children, and adolescents is usually intended as a prophylactic strategy to prevent bleeding (Table 123-3). More often in preterm neonates, platelet transfusions are performed for a therapeutic indication with platelet counts less than 50,000/μL during active bleeding. The prophylactic platelet transfusion thresholds in this group of patients are quite controversial and based primarily on expert consensus rather than evidenced-based medicine. In sharp contrast to adults, who rarely have severe bleeding as a complication until their platelet counts fall below 10,000/μL, preterm infants with other complicating illnesses may bleed at higher platelet counts. The increased risk may be secondary to (1) lower levels of plasma coagulation factors, (2) natural anticoagulants that potentiate thrombin inhibition, (3) intrinsic or extrinsic platelet dysfunction, and (4) increased vascular fragility. Platelet counts and function in older children are similar to those of adults, and the indications for platelet transfusions do not differ from the indications for adults.

Frozen Plasma and Cryoprecipitate

Frozen plasma is used in preterm and term infants most commonly to treat multiple factor deficiencies (vitamin K–dependent factors II, IV, IX, and X as well as proteins C and S), hemorrhagic disease of the newborn, or vitamin K deficiency (Table 123-4). ABO compatibility of the unit is especially important in pediatrics because transfused antibodies can reach high concentrations in infants and children with very small plasma volumes. Dosing is the same for neonates less than 4 months of age and those older: 10 to 15 mL/kg. The expected result is an increase in all factor activity by 15% to 20% unless there is a marked consumptive coagulopathy.

Cryoprecipitate is used primarily to treat disorders resulting from a decrease or dysfunction of fibrinogen or factor XIII deficiency. These indications are similar to those for adults. The important part for children is that it takes only a small volume of cryoprecipitate to increase the fibrinogen. One unit of cryoprecipitate is usually sufficient to achieve hemostatic levels in infants and even less than that in preterm infants. In children 1 to 2 units/10 kg is the dose. The expected rise in fibrinogen should be 60 to 100 mg/dL, assuming 100% recovery. When being administered to infants, cryoprecipitate should also be ABO compatible for the same reasons as mentioned for frozen plasma.

Table 123-3 Guidelines for Transfusion of Platelets in Neonates and Older Children

PLATELET COUNT <150,000/ML

1. Platelet count 5000-10,000/μL with failure of platelet production
2. Platelet count <30,000/μL in neonate with failure of platelet production
3. Platelet count <50,000/μL in stable premature infant
 a. With active bleeding, or
 b. Before an invasive procedure with failure of platelet production
4. Platelet count <100,000/μL in sick premature infant
 a. With active bleeding, or
 b. Before an invasive procedure in patient with DIC

WITHOUT THROMBOCYTOPENIA

1. Active bleeding with qualitative platelet defect
2. Unexplained excessive bleeding during cardiopulmonary bypass
3. Patient receiving ECMO with
 a. Platelet count <100,000/μL
 b. Higher platelet counts and bleeding

DIC, Disseminated intravascular coagulation; *ECMO,* extracorporeal membrane oxygenation.

Granulocytes

Neonatal granulocyte transfusions for sepsis remain unclear. Granulocytes are sometimes transfused for patients older than 4 months, although the benefit has not been clearly demonstrated in trials with modern antimicrobial therapy. The rationale in this population is that granulocytes may help support patients with persistent neutropenia or granulocyte dysfunction in the context of bacterial and/or fungal infection. The minimum dose of granulocytes for larger children and adults is 1×10^{10} cells/kg. The following are guidelines for transfusion of granulocytes to neonates and older children: (1) neonates or children with neutropenia or granulocyte dysfunction (e.g., chronic granulomatous disease) with bacterial sepsis and lack of responsiveness to standard therapy, and (2) neutropenic neonates or children with fungal disease not responsive to standard therapy (see Chapter 115).

TRANSFUSION MEDICINE: INDICATIONS IN UNIQUE PEDIATRIC POPULATIONS

Hemolytic Disease of the Fetus and Newborn

Hemolytic disease of the fetus and newborn (HDFN) occurs when the mother's immune system recognizes a foreign, paternally inherited antigen on fetal erythrocytes. The incidence of HDFN dramatically declined after the introduction of Rh immune globulin to prevent sensitization of the mother to RhD. Although introduction of Rh immune globulin has prevented most cases of HDFN due to RhD sensitization, it has not totally eliminated HDFN due to RhD or reduced HDFN due to other antibodies.

Table 123-4 Guidelines for Transfusion of Frozen Plasma and Cryoprecipitate in Neonates and Older Children

FROZEN PLASMA

1. Support during treatment of DIC
2. Replacement therapy
 a. When specific factor concentrates are not available, including but not limited to, antithrombin, protein C or S deficiency, and factor II, factor V, factor X, and factor XI deficiencies
 b. During therapeutic plasma exchange when FFP is indicated (cryoprecipitate-poor plasma, plasma from which the cryoprecipitate has been removed)
3. Reversal of warfarin in an emergency situation, such as before an invasive procedure with active bleeding

Note: Frozen plasma is not indicated for volume expansion or enhancement of wound healing

CRYOPRECIPITATE

1. Hypofibrinogenemia or dysfibrinogenemia with active bleeding
2. Hypofibrinogenemia or dysfibrinogenemia, undergoing an invasive procedure
3. Factor XIII deficiency with active bleeding or undergoing an invasive procedure in the absence of factor XIII concentrate
4. Limited directed-donor cryoprecipitate for bleeding episodes in small children with hemophilia A (when recombinant and plasma-derived factor VIII products are not available)
5. In the preparation of fibrin sealant
6. von Willebrand disease with active bleeding:
 Cryoprecipitate is used in von Willebrand disease only when both of the following are true:
 a. 1-Deamino-8-D-arginine vasopressin is contraindicated, not available, or does not elicit response
 b. Virus-inactivated plasma-derived factor VIII concentrate (which contains von Willebrand factor) is not available

DIC, Disseminated intravascular coagulation; *FFP,* fresh frozen plasma.

Blood-bank studies are critical in the diagnosis of this syndrome in both fetuses and newborns. Most significant cases of HDFN are due to antibodies outside of the ABO system. These antibodies will be detected in the blood of the pregnant or postpartum woman. Also necessary for the diagnosis, the corresponding antigens would be present on fetal or newborn erythrocytes, or predicted to be present on fetal erythrocytes based on molecular testing of fetal deoxyribonucleic acid (DNA). The direct antiglobulin test (DAT) of the fetal or newborn's erythrocytes should be positive. Additional testing is performed to determine the severity of fetal anemia, if present.

Although antibody titers are used to help predict the severity of the disease during pregnancy, they are generally not useful in the newborn. After birth, the severity of the anemia and the resulting hyperbilirubinemia serve as markers for the severity of the HDFN. Rates of rise in bilirubin level are most helpful in determining whether an exchange transfusion will be necessary, with increases of 8 to 13 μmol/L/hr despite phototherapy indicating that exchange transfusion will likely be necessary.[5]

RBCs transfused in utero to the fetus need to be compatible with the ABO type of the fetus and mother and hence are usually blood group O. They need to lack the antigen(s) to which the mother has made antibodies, and they need to be crossmatch compatible with her serum. The RBCs should be irradiated to prevent transfusion-associated graft-versus-host disease (TA-GVHD) and cytomegalovirus (CMV) safe to minimize the risk for transfusion-transmitted CMV. Relatively fresh RBCs also are usually chosen for these transfusions.

Reconstituted whole blood is usually used for neonatal exchange transfusions. The blood is prepared by removing most of the preservative solution from an RBC unit and adding plasma, usually so that the final hematocrit is 40% to 45%. Intrauterine transfusions are irradiated, and most institutions will select CMV-safe units (leukoreduced and/or CMV seronegative).

Neonatal Alloimmune Thrombocytopenia

The pathophysiology of neonatal alloimmune thrombocytopenia (NAIT) is similar to that of HDFN in that both involve immune-mediated attack and destruction of fetal and neonatal blood cells by the mother's immune system. Unlike HDFN, NAIT often affects a woman's first pregnancy. In addition, the antigens involved are due to polymorphisms on platelet-specific proteins. Although a variety of antigens can be implicated, the human platelet antigen-1 (HPA-1) protein is most frequently implicated in whites, with approximately 80% to 90% of cases being due to women who lack the HPA-1a antigen making antibodies against HPA-1a that is expressed on fetal platelets. When NAIT is suspected, maternal serum can be tested for antibodies to platelet antigens, and the parent's platelet antigens can be determined by testing their platelets or by molecular means in which their platelet antigens are indirectly determined from their DNA. An affected infant or fetus may require platelet transfusions. Although random platelets may be of some transient benefit, antigen-negative units are best. Maternal platelets lack the antigen, but the plasma contains the pathogenic antibody, which means that if maternal platelets are used, they should be washed before transfusion. Alternatively, antigen-negative units may be available. Indeed, major blood centers usually have HPA-1a-negative units available.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) is an intervention in which whole blood is removed from the patient's venous circulation and circulated through a machine to remove carbon dioxide and replenish oxygen before it is returned to the patient. This prolonged intervention is reserved for patients with more than 80% mortality risk and those who have been unresponsive to conventional ventilator support and medical treatment but still potentially have a reversible outcome. In neonates and children, ECMO has become a lifesaving therapy in the treatment of multiple disorders; Table 123-5[6] lists indications for ECMO support in neonates and children. Standardized guidelines for transfusion practice have not been established, resulting in individualized centers establishing their own criteria. Bleeding during ECMO is a common complication and may be caused by any of the following factors necessary for operating the ECMO circuit or resulting from the thrombogenic surface of the circuit: (1) systemic heparinization, (2) platelet dysfunction, (3) thrombocytopenia, (4) other coagulation defects, and (5) nonendothelial cell surface lining the circuitry. It is recommended that hospital transfusion services and ECMO staff be in close communication to agree on local protocols to ensure safe, efficient, and consistent care (Table 123-6 provides an example protocol from one institution).[6] Blood products for ECMO are typically ABO and Rh specific and crossmatch compatible for priming. The RBC units are hemoglobin S negative, relatively fresh, between 5 and 7 days old, irradiated, and CMV seronegative and/or leukoreduced.

Table 123-5 Indications for Extracorporeal Membrane Oxygenation for Neonates and Pediatric Patients

NEONATAL
Meconium aspiration
Respiratory distress syndrome
Persistent pulmonary hypertension
Congenital diaphragmatic hernia
Sepsis
PEDIATRIC
Bacterial pneumonia
Viral pneumonia
Acute respiratory distress syndrome
Burns
Inhalation injuries
Near drowning
Sepsis

Trauma

Transfusion management of a trauma patient often must be guided by the patient's estimated blood loss and associated signs and symptoms, such as hypotension or tachycardia. This topic has been the source of significant controversy in recent years, with retrospective studies from the U.S. military suggesting that ratios of 1:1 to 1:2 of plasma:RBCs and similar ratios of platelets:RBCs transfused during early treatment improves outcomes. Although there is significant criticism concerning inherent limitations in the retrospective nature of these studies, these transfusion strategies have been adopted by many adult trauma centers. Although some have advocated adopting similar protocols for pediatric trauma centers, this has occurred in only a few places, most likely because there are little data on transfusions in pediatric trauma patients.[7]

Hemoglobinopathies

In patients with sickle cell disease (SCD), chronic transfusion therapy has been shown to reduce the risk for both primary and secondary stroke, by decreasing the hemoglobin S content of the patient's blood, as well as achieving a reduction in sickling, suppression of erythropoiesis, and preventing an increase in blood viscosity.[8] The risk for recurrent stroke has been reduced to less than 10% if hemoglobin levels are maintained between 8 and 9 g/dL and hemoglobin S levels below 30%. Simple or partial-exchange transfusion therapy can achieve this goal when performed approximately every 3 to 4 weeks. Chronic erythrocytapheresis has also been used for this therapy with

Table 123-6 Blood Product Protocols for Extracorporeal Membrane Oxygenation

Clinical Scenario	Urgency	Products	Blood Groups	Storage
Cardiac arrest	5-10 min	2 units RBCs	O-negative RBCs	<14 days, AS
ECMO circuit disruption	5-10 min	2 units RBCs	O-negative RBCs	<14 days, AS
Progressive septic shock, nonneonate	30 min	2 units RBCs	O-negative RBCs or type specific	<10 days, any preservative
Neonate transferred for ECMO	1-2 hr	2 units RBCs 1 unit FFP 1 unit platelets	O-negative RBCs AB plasma	<10 days, CPD or CPDA-1
Cardiac ICU	30-60 min	2 units RBCs	Type specific	<7 days, AS
Gradual respiratory or cardiac failure on conventional support	Hours-days	2 units RBCs	Type specific	<10 days, CPD

AS, additive solution unit is acceptable; *CPD,* citrate phosphate dextrose; *CPDA-1,* citrate phosphate dextrose adenine; *ICU,* intensive care unit; *RBC,* red blood cell.

an added mission to mitigate iron overload complications. Chronic transfusion treatment for stroke most times is an indefinite therapy, that is, once the patient is placed on it, cessation is not possible because it has been shown to lead to recurrent stroke.[9] Table 123-2 describes other indications for patients with SCD needing either simple or chronic RBC transfusion therapy. Products for patients with SCD should be screened at a minimum for hemoglobin S and should be leukocyte reduced to reduce the risk for febrile nonhemolytic transfusion reactions and to reduce the risk for human leukocyte antigen (HLA) alloimmunization resulting in platelet refractoriness that can complicate possible stem cell transplantation.

In children with SCD, it also is critically important to prevent the alloimmunization to minor RBC antibodies, because, in most children with severe SCD, RBC transfusion is the only therapy available to treat the multiple manifestations of SCD. Overall, the SCD patient has higher rates of alloimmunization than other chronically transfused patient groups. The antibodies are produced against common Rh, Kell, Duffy, and Kidd system antigens. Many sickle cell treatment centers perform thorough phenotype analysis of a patient's red cells before initiating transfusion therapy. This testing helps to reduce the rate of alloimmunization by allowing preferential selection of phenotypically similar units.[10] However, particularly for patients who are not yet alloimmunized, this process remains controversial because phenotypically compatible units may be difficult to obtain and expensive.[11] The most common protocol followed for nonalloimmunized patients is pretransfusion phenotypic matching for C, E, and K antigens to prevent alloimmunization. In addition, some centers extend the protocol so that once patients have developed a red cell antibody, extension of matching to additional red cell antigens (Fy, Jk, S) is often used to prevent further alloimmunization. Furthermore, a recent retrospective study in children with SCD undergoing matched-sibling donor-related bone marrow transplantation demonstrated a decrease in RBC transfusion requirements during transplant when they received phenotypically minor RBC antigen–matched units.[12]

The benefits of RBC transfusion therapy in SCD disease must constantly be weighed against the costs (e.g., iron overload, RBC alloimmunization, and increased donor exposure risks of erythrocytapheresis). As a result of these issues, some clinicians have proposed that a clinically successful course of transfusions that maintains the hemoglobin S below 30% could, after several years, be transitioned to a strategy of more limited transfusions with a hemoglobin S target of 40% to 50% to reduce the risks for iron overload.[8] Patients with SCD may also be at risk for life-threatening delayed hemolytic transfusion reactions, the development of autoantibodies, and "hyperhemolytic" syndrome (a phenomenon that occurs after RBC transfusion when the patient's hemoglobin level unexpectedly decreases after transfusion and the cells that are destroyed are both the allogeneic and autologous cells). The mechanism is not well characterized.

Thalassemia

Thalassemia with severe anemia is usually treated with chronic transfusion therapy to improve tissue oxygenation and suppress extramedullary erythropoiesis in the liver, spleen, and bone marrow. This approach mitigates many of the complications caused by the ineffective erythropoiesis. In contrast to chronic transfusion regimens used to treat SCD, most β-thalassemia major patients requiring chronic transfusion therapy start at a very young age and require lifelong treatment. The treatment goals in this population are characterized by (1) increasing oxygen-carrying capacity by anemia correction, (2) preventing progressive hypersplenism, (3) suppression of endogenous erythropoiesis, and (4) reduction of gastrointestinal absorption of iron.[13] The target hemoglobin levels are usually 8 to 9 g/dL, where normal growth and development can occur in these patients. Supertransfusion protocols aim for higher target hemoglobin levels (11 to 12 g/dL) to reduce organomegaly from extramedullary hematopoiesis. Iron overload is a potential complication of this RBC transfusion protocol that cannot be prevented and must be treated with chelation therapy beginning early in childhood. RBC alloimmunization in this population is estimated at approximately 16%, which is half that of the rate for patients with SCD.[14] Phenotypic-matching protocols are used in some locations to prevent RBC alloimmunization, but data supporting or refuting this practice are scant.

Autoimmune Hemolytic Anemia

Autoimmune hemolytic anemia in children occurs predominantly in young children, with a median age of 3.8 years, and 53% are associated with other immunologic diseases, according to one study.[15] This study also found that 74% of the cases had DAT results that were positive for immunoglobulin G (IgG) and C3d. Like adult cases, most cases of autoimmune hemolytic anemia in children have antibody reactivity with all screening cells and all RBCs on antibody identification panels (i.e., positive indirect Coombs tests).

Children also may develop autoimmune hemolytic anemia associated with a Donath-Landsteiner antibody, an antibody that is rarely seen in adults. Classically the Donath-Landsteiner antibody is associated with paroxysmal cold hemoglobinuria, a disease in which patients developed paroxysms of hemoglobinuria following exposure

to cold temperatures.[16] Although this is often true, this classic syndrome is not always seen in children with the Donath-Landsteiner antibody. The syndrome often develops following an infection such as a respiratory infection.

The Donath-Landsteiner antibody is an IgG antibody that binds erythrocytes, usually recognizing the P antigen, at cold temperatures (<20° C [68° F]) and fixes early components of complement. The fixed complement does not cause significant hemolysis at cold temperatures, but when the cells are warmed, the entire complement complex binds and lyses the erythrocytes. Initial testing in the blood bank may be entirely normal or may reveal a positive DAT for C3. The Donath-Landsteiner antibody can be detected only by special testing in which the patient's plasma is incubated with erythrocytes in cold temperatures followed by warm temperatures (see Chapter 44).

Hematopoietic Cellular Transplant Patients

Transfusion support for HPC transplant patients is similar to that for adult patients, although there are few published studies on transfusion of pediatric HPC transplant patients. RBC transfusions are generally not needed in these patients whose hemoglobin level is at least 7 g/dL.[4] No studies in the modern era have been published on platelet transfusions in these patients, but use of a transfusion trigger of 10,000 platelets/μL, like that used for adults, seems reasonable for those patients without a significant bleeding risk other than thrombocytopenia.

Apheresis

Pediatric apheresis is used for many of the same indications as for adults. However, additional aspects need to be considered in treating pediatric patients. Many children require vascular access through a central vein because the peripheral veins of many children are too small. In addition, peripheral access requires patients to remain seated with the limited arm movement for the procedure duration, and younger patients are often unable to comply with this given that procedures usually last at least 2 hours. During the procedures, children are more susceptible to symptomatic hypocalcemia from citrate anticoagulation. For this reason, some pediatric centers use heparin to anticoagulate patients, although prophylactic cation replacement can successfully prevent most symptoms in pediatric apheresis patients.[17] Apheresis procedures subject the patient to volume shifts, which are usually a loss of less than 200 mL of fluid during the procedure and a gain of up to 300 mL at the end of the procedure. The actual fluid shifts depend on the machine, the procedure, and the parameters for that procedure. In some cases, the volume shifts may be too large to be safe for the patient. In these cases, most machines can be primed with 5% albumin, an RBC unit, or reconstituted whole blood. Using a prime solution, it is possible to minimize fluid shifts so that the patient is effectively volume neutral for the entire procedure. Procedures to accomplish this are usually only available at centers that perform apheresis on relatively large numbers of pediatric patients.

Special Processing and Prevention of Adverse Events in Pediatric Patients

In pediatric transfusion medicine, special processing of blood products is performed more often than in adults. This is especially true in the preterm infant population, specifically in very low-birth-weight (VLBW) infants weighing less than 1500 g and extremely low-birth-weight infants weighing less than 1000 g.

Leukocyte-Reduced Blood Components

Leukoreduced cellular blood products are used in greater than 80% of blood components transfused to children in the United States, despite a paucity of clinical studies in children.[18] The rationale behind the use in pediatric patients has primarily been extrapolated from adult studies. Leukoreduction is performed to reduce transmission of CMV, decrease HLA alloimmunization,[19] and decrease febrile nonhemolytic transfusion reactions. From an evidence-based medicine approach, leukoreduction still remains controversial, because transfusion reactions in neonates younger than 4 months of age occur infrequently and infants rarely become HLA alloimmunized due to their immature immune system. Nonetheless, one known benefit of leukoreduced cellular products is reduction in the risk for transfusion-transmitted CMV.[20] In Canada, Fergusson et al[21] evaluated clinical outcomes of premature infants weighing less than 1250 g, before and after nationwide implementation of universal leukoreduction, revealing no changes in mortality or rate of bacteremia. However, the study revealed a decrease in retinopathy of prematurity, bronchopulmonary dysplasia, and length of hospitalization after implementation.[21]

Cytomegalovirus-Seronegative Blood Components

The provision of CMV-seronegative blood products to certain pediatric populations is based on prevention of transfusion transmission of CMV. The residual risk for transfusion-transmitted CMV in adults has been estimated to be between 1% and 3%. In preterm neonates, transfusing CMV-seronegative blood components has been shown to be extremely effective in reducing the risk for CMV infection in multitransfused infants weighing less than 1200 g born to seronegative mothers.[22] Based on this study primarily, it is recommended that infants born to CMV-seronegative mothers receive CMV–reduced risk blood for transfusions. The accepted strategies for CMV–reduced risk transfusions are CMV-seronegative or CMV-leukoreduced products. Many neonatologists in the United States combine the strategies, hoping to improve prevention of transfusion-transmitted CMV. However, in 2001 the Canadian Consensus Conference did not issue a recommendation for a combined use of leukoreduction plus CMV-seronegative allogeneic blood for low-birth-weight (LBW) infants. The combined approach for prevention of transfusion-transmitted CMV was recommended for the following groups: transfusions to CMV-seronegative pregnant women, intrauterine fetal transfusions, and CMV-seronegative allogeneic bone marrow transplantation recipients. Nonetheless, the scientific question of whether the combined strategy reduces the risk for transfusion-transmitted CMV in any vulnerable population is yet to be answered. Currently a large prospective birth cohort study in VLBW infants is under way to estimate the incidence of transfusion-transmitted CMV in LBW infants who receive CMV-seronegative plus leukoreduced blood products to evaluate the effectiveness of this coupled strategy.

Irradiation

Mortality rates associated with TA-GVHD are as high as 80% to 90%, with no effective treatments once it has occurred. As a result, identifying neonates and children who are either immunoincompetent or immunosuppressed is paramount, so irradiation of cellular components can be performed to prevent this noninfectious serious hazard of transfusion. There are differing expert opinions and practices in this area, and local protocols based on patient populations, equipment available, and best practices at each institution should be followed. The following are some guidelines for neonates and older children in this area: (1) premature infants with birth weight less than 1200 g, (2) any child with known or suspected cellular immune deficiency (e.g., severe combined immunodeficiency), (3) any child with significant immunosuppression due to chemotherapy or radiation treatment, (4) any child who receives blood components from blood relatives, and (5) any child who receives HLA-matched or crossmatched platelet components.

Washing

Washing is usually performed to reduce the risk for adverse reactions related to plasma, anticoagulant-preservative solutions, and high levels of potassium. Neonates and children in specific situations may require this intervention, but it should not be a routine practice. Washing, resulting in the removal or reduction of plasma, becomes critical when transfusing maternal blood to treat either hemolytic disease of the newborn or NAIT because the plasma contains the offending antibodies. Indeed, use of maternal blood for these patients is not recommended.

Volume Reduction

Volume reduction of plasma in a closed system is primarily a technique used in premature infants who have renal ischemia or compromised cardiac function. However, it is also employed for infants and children who may receive ABO-mismatched platelet transfusions, because several deaths have been reported in the literature of children who have received out-of-group platelets (e.g., O platelet pheresis to A recipient).[23]

Reconstitution of RBCs for Neonatal Exchange Transfusion

When the RBCs are being prepared for a neonatal exchange transfusion, the component choice and expected potential physiologic effects must be taken into consideration. Usually RBCs are resuspended in ABO-compatible thawed FFP. Typically, RBCs that are less than 5 to 7 days old and stored in citrate phosphate dextrose adenine (CPDA-1) solution are chosen to avoid high levels of potassium. Units provided are hemoglobin sickle negative to avoid potential for intravascular sickling and CMV seronegative to prevent transfusion-transmitted CMV; irradiation is performed to prevent TA-GVHD. The irradiation should be performed just before the exchange to minimize the potentiation of the potassium storage lesion. The glucose load during an exchange transfusion has been noted to be high; therefore it is recommended that in the first few hours of the exchange the infant's glucose levels be monitored.

The expected amount of RBCs needed for an infant double-volume exchange transfusion is approximately 1 unit of RBCs depending on the patient's weight. A final hematocrit of approximately 45% to 60% should be the target for the product. The reconstituted blood must be adequately mixed to maintain the intended hematocrit throughout the exchange transfusion.

When the exchange transfusion is being performed, a standard filter and inline blood warmer are recommended. A rule of thumb for withdrawal and infusion of blood during the exchange is usually no more than 5 mL/kg body weight or 5% of the infant's blood volume is to be removed and replaced during a 3- to 5-minute cycle. The exchange should be performed at a slow pace, so as to not cause sudden hemodynamic changes that can result in cerebral blood flow shifts in intracranial pressure, precipitating an intraventricular hemorrhage.[24] The expected total time for a double-volume exchange transfusion is typically around 1½ to 2 hours.

CHAPTER 124

OVERVIEW OF HEMOSTASIS AND THROMBOSIS

Jeffrey I. Weitz

Hemostasis preserves vascular integrity by balancing the physiologic processes that maintain blood in a fluid state under normal circumstances and prevent excessive bleeding after vascular injury. Preservation of blood fluidity depends on an intact vascular endothelium and a complex series of regulatory pathways that maintains platelets in a quiescent state and keeps the coagulation system in check. In contrast, arrest of bleeding requires rapid formation of hemostatic plugs at sites of vascular injury to prevent exsanguination. Perturbation of hemostasis can lead to bleeding or thrombosis. Bleeding will occur if there is failure to seal vascular leaks either because of defective hemostatic plug formation or because of premature breakdown of the plugs. In contrast, thrombosis may occur if prothrombotic stimuli are unregulated.

Thrombosis can occur in arteries or veins and is a major cause of morbidity and mortality. Arterial thrombosis is the most common cause of acute coronary syndromes, ischemic stroke, and limb gangrene, but thrombosis in the deep veins of the leg leads to the postthrombotic syndrome and to pulmonary embolism, which can be fatal.

Most arterial thrombi form on top of disrupted atherosclerotic plaques because plaque rupture exposes thrombogenic material in the plaque core to the blood.[1] This material then triggers platelet aggregation and fibrin formation, which results in the generation of a platelet-rich thrombus that temporarily or permanently occludes blood flow. Whereas temporary occlusion of blood flow in coronary arteries may trigger unstable angina, persistent obstruction causes myocardial infarction. The same processes can occur in the cerebral circulation, where temporary arterial occlusion may manifest as a transient ischemic attack and persistent occlusion can lead to a stroke. Likewise, critical limb ischemia can occur if there is superimposed thrombosis on ruptured atherosclerotic plaques in the major arteries supplying blood to the lower extremities.

In contrast to arterial thrombi, venous thrombi rarely form at sites of obvious vascular disruption. Although they can develop after surgical trauma to veins or secondary to indwelling venous catheters, they usually originate in the valve cusps of the deep veins of the calf or in the muscular sinuses, where there is stasis.[2] Sluggish blood flow in these veins reduces the oxygen supply to the avascular valve cusps. Hypoxemia induces endothelial cells lining the valve cusps to express adhesion molecules, which tether tissue factor-bearing leukocytes and microparticles onto their surface. Tissue factor–bearing leukocytes and microparticles adhere to these activated cells and induce coagulation. Impaired blood flow exacerbates local thrombus formation by reducing clearance of activated clotting factors. Calf vein thrombi that extend into the proximal veins of the leg can dislodge and travel to the lungs to produce pulmonary embolism.[3]

Arterial and venous thrombi contain platelets and fibrin, but the proportions differ. Arterial thrombi are rich in platelets because of the high shear in the injured arteries. In contrast, venous thrombi, which form under low shear conditions, contain relatively few platelets and consist mostly of fibrin and trapped red blood cells. Because of the predominance of platelets, arterial thrombi appear white, but venous thrombi appear red, reflecting the trapped red cells.

The antithrombotic drugs used for prevention and treatment of thrombosis target components of thrombi, and include antiplatelet drugs, which inhibit platelets; anticoagulants, which attenuate coagulation; and fibrinolytic agents that induce fibrin degradation (see Chapter 151). With the predominance of platelets in arterial thrombi, strategies to inhibit or treat arterial thrombosis focus mainly on antiplatelet agents, although in the acute setting, strategies often include anticoagulants and fibrinolytic agents. When arterial thrombi are occlusive and rapid restoration of blood flow is required, mechanical and pharmacologic methods enable thrombus extraction, compression, or degradation (see Chapter 145). Although rarely used for this indication, anticoagulants can also prevent recurrent ischemic events after acute myocardial infarction. Anticoagulants are the mainstay for prevention and treatment of venous thromboembolism because fibrin is the predominant component of venous thrombi (see Chapter 144). Antiplatelet drugs are less effective than anticoagulants because of the limited platelet content of venous thrombi. Selected patients with venous thromboembolism benefit from fibrinolytic therapy—for example, patients with massive or submassive pulmonary embolism achieve more rapid restoration of pulmonary blood flow with systemic or catheter-directed fibrinolytic therapy than with anticoagulant therapy alone. Selected patients with extensive deep vein thrombosis in the iliac or femoral veins also may have a better outcome with catheter-directed fibrinolytic therapy or mechanical thrombus extraction in addition to anticoagulants (see Chapter 145).

This chapter provides an overview of hemostasis and thrombosis and highlights the processes involved in platelet activation and aggregation, blood coagulation, and fibrinolysis.

HEMOSTATIC SYSTEM

The major components of the hemostatic system are the vascular endothelium, platelets, and the coagulation and fibrinolytic systems.

Vascular Endothelium

A monolayer of endothelial cells lines the intimal surface of the circulatory tree and separates the blood from the prothrombotic subendothelial components of the vessel wall (see Chapter 125). As such, the vascular endothelium encompasses about 10^{13} cells and covers a vast surface area. Rather than serving as a static barrier, the healthy vascular endothelium is a dynamic organ (Fig. 124-1) that actively regulates hemostasis by inhibiting platelets, suppressing coagulation, promoting fibrinolysis, and modulating vascular tone and permeability.[4] Defective vascular function can lead to bleeding if the endothelium becomes more permeable to blood cells, if vasoconstriction does not occur, or if premature degradation of hemostatic plugs opens seals in the vasculature.

Platelet Inhibition

Endothelial cells synthesize prostacyclin and nitric oxide and release them into the blood.[4] These agents not only serve as potent vasodilators but also inhibit platelet activation and subsequent aggregation

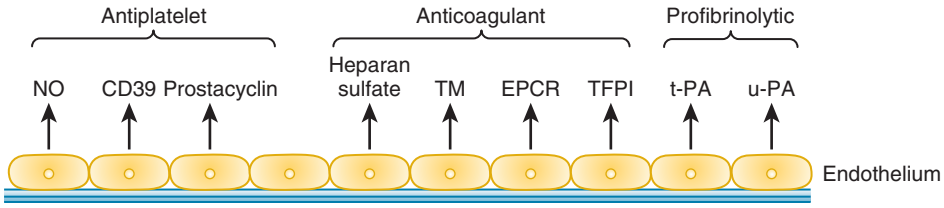

Figure 124-1 THE ANTITHROMBOTIC FUNCTIONS OF THE ENDOTHELIUM. The healthy endothelium has (1) antiplatelet activity because of synthesis and release of prostacyclin and nitric oxide (NO) and expression of CD39, a membrane-associated ectoADPase; (2) anticoagulant activity because of heparan sulphate proteoglycan-mediated activation of antithrombin and expression of thrombomodulin (TM) and endothelial protein C receptor (EPCR), which are involved in protein C activation, and surface-bound tissue factor pathway inhibitor (TFPI); and (c) profibrinolytic activity because of release of tissue and urokinase-type plasminogen activator (t-PA and u-PA, respectively).

by stimulating adenylate cyclase and increasing intracellular levels of cyclic adenosine monophosphate (cAMP). In addition, endothelial cells express CD39 on their surface, a membrane-associated ecto-adenosine diphosphatase (ADPase). By degrading ADP, which is a platelet agonist, CD39 attenuates platelet activation.

Anticoagulant Activity

Intact endothelial cells play an essential part in the regulation of thrombin generation through a variety of mechanisms. Endothelial cells produce heparan sulfate proteoglycans, which bind circulating antithrombin and accelerate the rate at which it inhibits thrombin and other coagulation enzymes. Tissue factor pathway inhibitor (TFPI), a naturally occurring inhibitor of coagulation, binds heparan sulfate on the endothelial cell surface.[5] Administration of heparin or low-molecular-weight heparin (LMWH) displaces glycosaminoglycan-bound TFPI from the vascular endothelium, and released TFPI may contribute to the antithrombotic activity of these drugs.

Endothelial cells regulate thrombin generation by expressing thrombomodulin and endothelial cell protein C receptor (EPCR) on their surfaces. Thrombomodulin binds thrombin and alters this enzyme's substrate specificity such that it no longer acts as a procoagulant but becomes a potent activator of protein C (see Chapter 129). Activated protein C serves as an anticoagulant by degrading and inactivating activated factor V and factor VIII (factors Va and VIIIa, respectively), key cofactors involved in thrombin generation. Protein S acts as a cofactor in this reaction, and EPCR enhances this pathway by binding protein C and presenting it to the thrombin–thrombomodulin complex for activation. In addition to its role as an anticoagulant, activated protein C also regulates inflammation and preserves the barrier function of the endothelium.[6]

Fibrinolytic Activity

The vascular endothelium promotes fibrinolysis by synthesizing and releasing tissue-type and urokinase-type plasminogen activator (t-PA and u-PA, respectively), which initiate fibrinolysis by converting plasminogen to plasmin (see Chapter 129). Endothelial cells in most vascular beds synthesize t-PA constitutively. In contrast, perturbed endothelial cells produce u-PA in the settings of inflammation and wound repair.

Endothelial cells also produce type 1 plasminogen activator inhibitor 1 (PAI-1), the major regulator of both t-PA and u-PA. Therefore, net fibrinolytic activity depends on the dynamic balance between the release of plasminogen activators and PAI-1. Fibrinolysis localizes to the endothelial cell surface because these cells express annexin II, a coreceptor for plasminogen and t-PA that promotes their interaction. Therefore, healthy vessels actively resist thrombosis and help maintain platelets in a quiescent state.

Vascular Tone and Permeability

In addition to synthesizing potent vasodilators, such as prostacyclin and nitric oxide, endothelial cells also produce a group of counter-regulatory peptides known as endothelins that induce vasoconstriction. Endothelial cell permeability is influenced by the connections that join endothelial cells to their neighbors. Macromolecules traverse the endothelium via patent intercellular junctions, by endocytosis, or through transendothelial pores. Vasodilatation, severe thrombocytopenia, and high doses of heparin can increase endothelial permeability, which may contribute to bleeding. Activated protein C may also contribute to the barrier function of the endothelium.

Platelets

Platelets are anucleate particles released into the circulation after fragmentation of bone marrow megakaryocytes (see Chapter 126). Because they are anucleate, platelets have limited capacity to synthesize proteins. Thrombopoietin, a glycoprotein synthesized in the liver and kidneys, regulates megakaryocytic proliferation and maturation as well as platelet production. After they enter the circulation, platelets have a life span of 7 to 10 days.

Damage to the intimal lining of the vessel exposes the underlying subendothelial matrix. Platelets home to sites of vascular disruption and adhere to the exposed matrix proteins (see Chapter 127). Adherent platelets undergo activation and not only release substances that recruit additional platelets to the site of injury but also promote thrombin generation and subsequent fibrin formation (Fig. 124-2). A potent platelet agonist, thrombin amplifies platelet recruitment and activation. Activated platelets then aggregate to form a plug that seals the leak in the vasculature.[7] An understanding of the steps in these highly integrated processes helps pinpoint the sites of action of the antiplatelet drugs and rationalizes the utility of anticoagulants for the treatment of arterial thrombosis and venous thrombosis.

Adhesion

Platelets adhere to exposed collagen and von Willebrand factor (vWF) and form a monolayer that supports and promotes thrombin generation and subsequent fibrin formation. These events depend on constitutively expressed receptors on the platelet surface, $\alpha_2\beta_1$ and glycoprotein (GP) VI, which bind collagen, and GPIbα and GPIIb/IIIa ($\alpha_{IIb}\beta_3$), which bind vWF. The platelet surface is crowded with receptors, but those involved in adhesion are the most abundant: every platelet has about 40,000 to 80,000 copies of GPIIb/IIIa and 25,000 copies of GPIbα. Receptors cluster in cholesterol-enriched subdomains, which render them more mobile, thereby increasing the efficiency of platelet adhesion and subsequent activation (see Chapter 127).

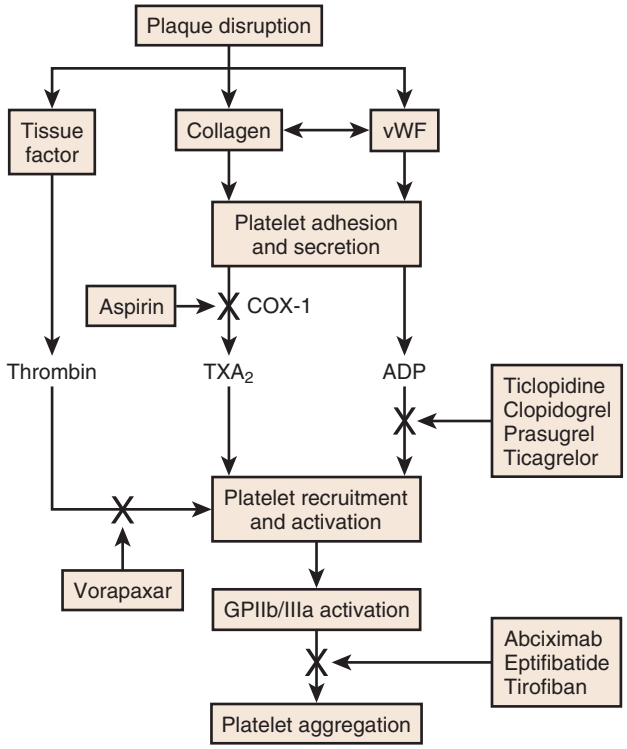

Figure 124-2 SITES OF ACTION OF ANTIPLATELET DRUGS. Aspirin inhibits thromboxane A_2 (TXA_2) synthesis by irreversibly acetylating cyclooxygenase-1 (COX-1). Reduced TXA_2 release attenuates platelet activation and recruitment to the site of vascular injury. Ticlopidine, clopidogrel, and prasugrel irreversibly block $P2Y_{12}$, a key adenosine diphosphate (ADP) receptor on the platelet surface; ticagrelor is a reversible inhibitor of $P2Y_{12}$. Apciximab, eptifibatide, and tirofiban inhibit the final common pathway of platelet aggregation by blocking fibrinogen and von Willebrand factor (vWF) binding to activated glycoprotein (GP) IIb/IIIa. Vorapaxar inhibits thrombin-mediated platelet activation by targeting protease activated receptor-1 (PAR-1), the major thrombin receptor on platelets.

Under low shear conditions, collagen can capture and activate platelets on its own. Captured platelets undergo cytoskeletal reorganization that causes them to flatten and to adhere more closely to the damaged vessel wall. Under high shear conditions, however, collagen and vWF must act in concert to support optimal platelet adhesion and activation. vWF synthesized by endothelial cells and megakaryocytes assembles into multimers that range from 550 to more than 10,000 kDa. When released from storage in the Weibel-Palade bodies of endothelial cells or the α-granules of platelets, most of the vWF enters the circulation, but the vWF released from the abluminal surface of endothelial cells accumulates in the subendothelial matrix, where it binds collagen via its A3 domain. This surface-immobilized vWF can simultaneously bind platelets via its A1 domain. In contrast, circulating vWF does not react with unstimulated platelets. This difference in reactivity likely reflects vWF conformation; whereas circulating vWF is in a coiled conformation that prevents access of its platelet-binding domain to vWF receptors on the platelet surface, immobilized vWF assumes an elongated shape that exposes its A1 domain. In this extended conformation, large vWF multimers serve as the molecular glue that tethers platelets to the damaged vessel wall with sufficient strength to withstand higher shear forces.[8] Large vWF multimers provide additional binding sites for collagen and heighten platelet adhesion because platelets have more vWF receptors than collagen receptors. Adhesion to collagen or vWF results in platelet activation, the next step in platelet plug formation.

Activation and Secretion

Adhesion to collagen and vWF initiates signaling pathways that result in platelet activation. These pathways induce cyclooxygenase-1 (COX-1)–dependent synthesis and release of thromboxane A_2, and trigger the release of adenosine diphosphate (ADP) from storage granules. Thromboxane A_2 is a potent vasoconstrictor, and similar to ADP, locally activates ambient platelets and recruits them to the site of injury. This process results in expansion of the platelet plug. To activate platelets, thromboxane A_2 and ADP must bind to their respective receptors on the platelet membrane. The thromboxane receptor (TP) is a G-protein coupled receptor that is found on platelets and on the endothelium, which explains why thromboxane A_2 induces vasoconstriction as well as platelet activation.[9] ADP interacts with a family of G protein–coupled receptors on the platelet membrane. Most important of these is $P2Y_{12}$, which is the target of the thienopyridines, but $P2Y_1$ also contributes to ADP-induced platelet activation, and maximal ADP-induced platelet activation requires activation of both receptors. A third ADP receptor, $P2X_1$, is an adenosine triphosphate (ATP)–gated calcium channel. Platelet storage granules contain ATP as well as ADP; ATP released during the platelet activation process may contribute to the platelet recruitment process in a $P2X_1$-dependent fashion.

Although TP and the various ADP receptors signal through different pathways, they all trigger an increase in the intracellular calcium concentration in platelets. This in turn induces shape change via cytoskeletal rearrangement, granule mobilization and release, and subsequent platelet aggregation. Activated platelets promote coagulation by expressing phosphatidylserine on their surfaces, an anionic phospholipid that supports assembly of coagulation factor complexes (see Chapter 128). After being assembled, these clotting factor complexes trigger a burst of thrombin generation and subsequent fibrin formation. In addition to converting fibrinogen to fibrin, thrombin amplifies platelet recruitment and activation and promotes expansion of the platelet plug. Thrombin binds to protease-activated receptors types 1 and 4 (PAR1 and PAR4, respectively) on the platelet surface and cleaves their extended amino-termini, thereby generating new amino-termini that serve as tethered ligands that bind and activate the receptors (Fig. 124-3). Whereas low concentrations of thrombin cleave PAR1, PAR4 cleavage requires higher thrombin concentrations.[10] Cleavage of either receptor triggers platelet activation.

In addition to providing a surface on which clotting factors assemble, activated platelets also promote fibrin formation and subsequent stabilization by releasing factor V, factor XI, fibrinogen, and factor XIII (see Chapter 127). Thus, there is coordinated activation of platelets and coagulation, and the fibrin network that results from thrombin action helps anchor the platelet aggregates at the site of injury. Activated platelets also release adhesive proteins, such as vWF, thrombospondin, and fibronectin, which may augment platelet adhesion at sites of injury, as well as growth factors, such as platelet-derived growth factor (PDGF) and transforming growth factor-β (TGFβ), which promote wound healing. Platelet aggregation is the final step in the formation of the platelet plug.

Aggregation

Platelet aggregation links platelets to each other to form clumps. GPIIb/IIIa mediates these platelet-to-platelet linkages. On nonactivated platelets, GPIIb/IIIa exhibits minimal affinity for its ligands. Upon platelet activation, GPIIb/IIIa undergoes a conformational transformation, which reflects transmission of inside-out signals from its cytoplasmic domain to its extracellular domain.[11] This transformation enhances the affinity of GPIIb/IIIa for its ligands; fibrinogen; and, under high shear conditions, vWF (see Chapter 127). Arginine–glycine–aspartic acid (RGD) sequences located on fibrinogen and vWF, as well as a platelet-binding lycine–glycine–aspartic acid (KGD) sequence on fibrinogen, mediate their interaction with GPIIb/IIIa. When subjected to high shear, circulating vWF elongates and exposes its platelet-binding domain, which enables its interaction with the

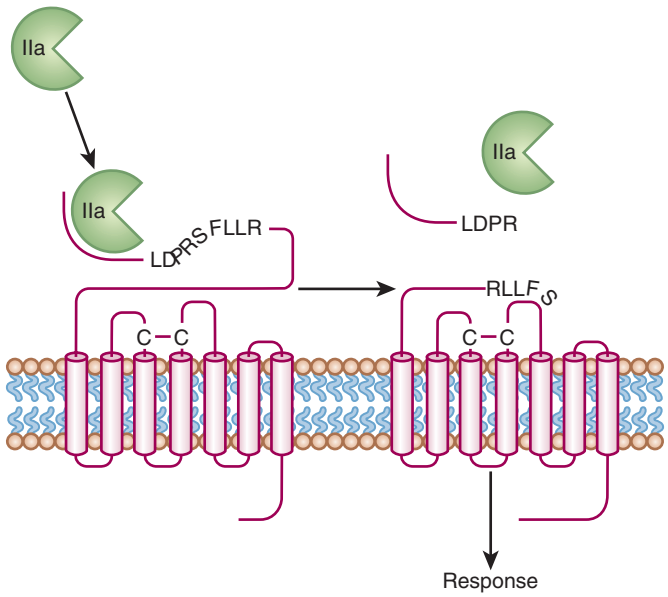

Figure 124-3 ACTIVATION OF PROTEASE-ACTIVATED RECEPTOR (PAR)-1 BY THROMBIN. Thrombin (IIa) binds to the amino terminus of the extracellular domain of PAR-1, where it cleaves a specific peptide bond. Cleavage of this bond generates a new amino-terminus sequence that acts as a tethered ligand and binds to the body of the receptor, thereby activating it. Thrombin then dissociates from the receptor. Analogs of the first five or six amino acids of the tethered ligand sequences, known as thrombin receptor agonist peptides, can independently activate PAR-1.

conformationally activated GPIIb/IIIa. Divalent fibrinogen and multivalent vWF molecules serve as bridges and bind adjacent platelets together. After being bound to GPIIb/IIIa, fibrinogen and vWF induce outside–inside signals that augment platelet activation and result in the activation of additional GPIIb/IIIa receptors, creating a positive feedback loop. Because GPIIb/IIIa acts as the final effector in platelet aggregation, it is a logical target for potent antiplatelet drugs (see Chapters 132 and 151). Fibrin, the ultimate product of the coagulation system, tethers the platelet aggregates together and anchors them to the site of injury.

Coagulation

Coagulation results in the generation of thrombin, which converts soluble fibrinogen to fibrin. Coagulation occurs through the action of discrete enzyme complexes, which are composed of a vitamin K-dependent enzyme and a non-enzyme cofactor, and assemble on anionic phospholipid membranes in a calcium-dependent fashion (see Chapter 128). Each enzyme complex activates a vitamin K–dependent substrate that becomes the enzyme component of the subsequent complex. Together, these complexes generate a small amount of thrombin, which amplifies its own generation by activating the non-enzyme cofactors and platelets, which then provide an anionic surface on which the complexes assemble. The three enzyme complexes involved in thrombin generation are extrinsic tenase, intrinsic tenase, and prothrombinase (Fig. 124-4). Although extrinsic tenase initiates the system under most circumstances, the contact system also plays a role in some situations.

Extrinsic Tenase

This complex forms upon exposure of tissue factor-expressing cells to the blood.[12] Tissue factor exposure occurs after atherosclerotic plaque rupture because the core of the plaque is rich in cells that express tissue factor. Denuding injury to the vessel wall also exposes tissue factor constitutively expressed by subendothelial fibroblasts and smooth muscle cells. In addition to cells in the vessel wall, circulating monocytes and monocyte-derived microparticles (small membrane fragments) also provide a source of tissue factor. When tissue factor–bearing monocytes or microparticles bind to platelets or other leukocytes and their plasma membranes fuse, tissue factor transfer occurs. By binding to adhesion molecules expressed on activated endothelial cells or to P-selectin on activated platelets, these tissue factor-bearing cells or microparticles can initiate or augment coagulation.[13] This phenomenon likely explains how venous thrombi develop in the absence of obvious vessel wall injury.

Tissue factor is an integral membrane protein that serves as a receptor for factor VIIa. The blood contains trace amounts of factor VIIa, which has negligible activity in the absence of tissue factor.[12] With tissue factor exposure on anionic cell surfaces, factor VIIa binds in a calcium-dependent fashion to form the extrinsic tenase complex, which is a potent activator of factors IX and X. After being activated, factor IXa and factor Xa serve as the enzyme components of intrinsic tenase and prothrombinase, respectively.

Intrinsic Tenase

Factor IXa binds to factor VIIIa on anionic cell surfaces to form the intrinsic tenase complex.[14] Factor VIII circulates in blood in complex with vWF. Thrombin cleaves factor VIII and releases it from vWF, converting it to its activated form.[15] Activated platelets express binding sites for factor VIIIa. After being bound, factor VIIIa binds factor IXa in a calcium-dependent fashion to form the intrinsic tenase complex, which then activates factor X. The change in catalytic efficiency of factor IXa–mediated activation of factor X that occurs with deletion of individual components of the intrinsic tenase complex highlights their importance. Absence of the membrane or factor VIIIa almost completely abolishes enzymatic activity, and the catalytic efficiency of the complete complex is 10^9-fold greater than that of factor IXa alone.[14] Because intrinsic tenase activates factor X at a rate 50- to 100-fold faster than extrinsic tenase, it plays a critical role in the amplification of factor Xa and subsequent thrombin generation (see Chapter 128).

Prothrombinase

Factor Xa binds to factor Va, its activated cofactor, on anionic phospholipid membrane surfaces to form the prothrombinase complex. Activated platelets release factor V from their α-granules, and this platelet-derived factor V may play a more important role in hemostasis than its plasma counterpart.[16] Whereas plasma factor V requires thrombin activation to exert its cofactor activity, the partially activated factor V released from platelets already exhibits substantial cofactor activity. Activated platelets express specific factor Va binding sites on their surface, and bound factor Va serves as a receptor for factor Xa. The catalytic efficiency of factor Xa activation of prothrombin increases by 10^9-fold when factor Xa incorporates into the prothrombinase complex.[14] Prothrombin binds to the prothrombinase complex, where it undergoes conversion to thrombin in a reaction that releases prothrombin fragment 1.2 (F1.2). Plasma levels of F1.2, therefore, provide a marker of prothrombin activation.

Fibrin Formation

The final effector in coagulation is thrombin. Thrombin converts soluble fibrinogen into insoluble fibrin. Fibrinogen is a dimeric molecule, each half of which is composed of three polypeptide chains—the Aα, Bβ, and γ chains. Numerous disulfide bonds covalently link the chains together and join the two halves of the fibrinogen molecule (Fig. 124-5). Electron micrographic studies of fibrinogen reveal a trinodular structure with a central E domain flanked by two D

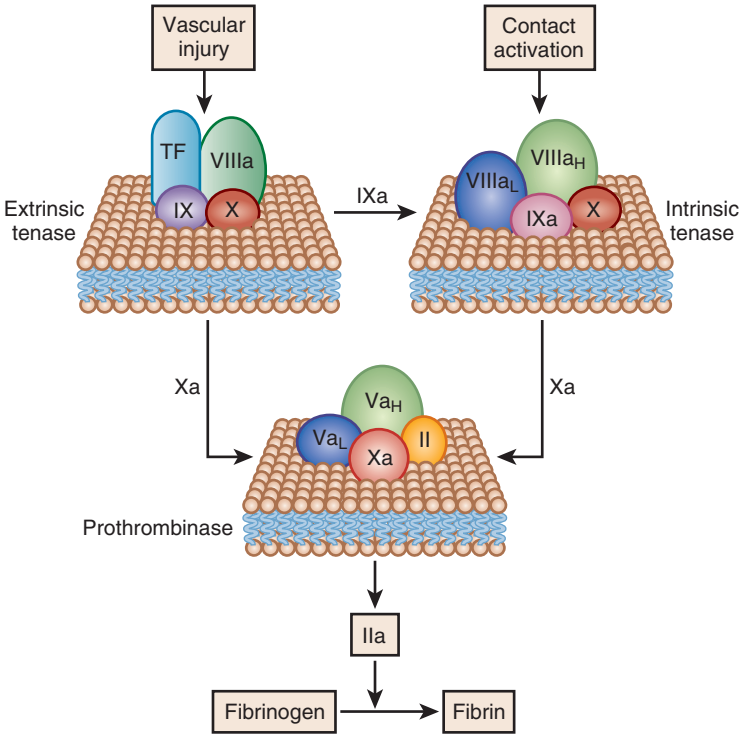

Figure 124-4 COAGULATION SYSTEM. Coagulation occurs through the action of discrete enzyme complexes, which are composed of a vitamin K–dependent enzyme and a non-enzyme cofactor. These complexes assemble on anionic phospholipid membranes in a calcium-dependent fashion. Vascular injury exposes tissue factor (TF), which binds factor VIIa to form extrinsic tenase. Extrinsic tenase activates factors IX and X. Factor IXa binds to factor VIIIa to form intrinsic tenase, which activates factor X. Factor Xa binds to factor Va to form prothrombinase, which converts prothrombin (II) to thrombin (IIa). Thrombin then converts soluble fibrinogen into insoluble fibrin.

domains. Crystal structures show symmetry of design with the central E domain, which contains the amino termini of the fibrinogen chains, joined to the lateral D domains by coiled-coil regions.

Fibrinogen circulates in an inactive form. Thrombin binds to the amino termini of the Aα and Bβ chains of fibrinogen, where it cleaves specific peptide bonds to release fibrinopeptide A and fibrinopeptide B and generates fibrin monomer (see Fig. 124-5). Because they are products of thrombin action on fibrinogen, plasma levels of these fibrinopeptides provide an index of thrombin activity. Fibrinopeptide release creates new amino termini that extend as knobs from the E domain of one fibrin monomer and insert into preformed holes in the D domains of other fibrin monomers. This creates long strands known as protofibrils, consisting of fibrin monomers noncovalently linked together in a half-staggered overlapping fashion.[17]

Noncovalently linked fibrin protofibrils are unstable.[17] The stability of the fibrin network is enhanced by platelets and procoagulant cells.[18] Platelets not only bind fibrin via GPIIb/IIIa and promote the formation of a dense fibrin network, but they also release factor XIII. By covalently cross-linking the α and γ chains of adjacent fibrin monomers, factor XIIIa stabilizes the fibrin in a calcium-dependent fashion and renders it relatively resistant to degradation. Factor XIII circulates in blood as a heterodimer consisting of pairs of A and B subunits. The active and calcium binding sites on factor XIII are localized to the A subunit. Platelets contain large amounts of factor XIII in their cytoplasms, but platelet-derived factor XIII consists only of the A subunits (see Chapter 127). Both plasma and platelet factor XIII are activated by thrombin.

Contact Pathway

Current thinking is that tissue factor exposure represents the sole pathway for activation of coagulation and that the contact system—which includes factor XII, prekallikrein, and high-molecular-weight kininogen—is unimportant for hemostasis because patients deficient in these factors do not have bleeding problems (see Chapter 139). The physiologic role of factor XI is more difficult to assess because the plasma level of factor XI does not predict the propensity for bleeding (see Chapter 139). Although the capacity of thrombin to feed back and activate platelet-bound factor XI may explain this phenomenon, platelet-derived factor XI may be more important for hemostasis than circulating factor XI.

We cannot ignore the contact pathway, however, because coronary catheters and other blood-contacting medical devices, such as stents or mechanical valves, likely trigger clotting through this mechanism. Factor XII bound to the surface of catheters or devices undergoes a conformational change that results in its activation. Factor XIIa converts prekallikrein to kallikrein in a reaction accelerated by high-molecular-weight kininogen, and factor XIIa and kallikrein then feedback to activate additional factor XII. Factor XIIa propagates coagulation by activating factor XI (Fig. 124-6).

In addition to its role in device-related thrombosis, the contact pathway may also contribute to the stability of arterial and venous thrombi.[19,20] DNA and RNA released from damaged cells in atherosclerotic plaques activates factor XII, and mice given DNA- or RNA-degrading enzymes exhibit attenuated thrombosis at sites of arterial injury. Polyphosphates released from activated platelets also activate factor XII and may provide another stimulus for contact pathway activation. Mice deficient in factor XII or factor XI form small unstable thrombi at sites of arterial or venous damage, suggesting that factor XII and factor XI contribute to thrombogenesis (see Chapter 139). It is unknown whether the same is true in humans. Patients with unstable angina have increased plasma levels of factor XIa, but it is unclear whether this reflects activation by factor XIIa or by thrombin. Although the contribution of the contact pathway to thrombin generation remains uncertain, the final product of coagulation is fibrin. Hemostasis depends on the dynamic balance between the formation of fibrin and its degradation. The fibrinolytic system mediates fibrin breakdown.

Fibrinolytic System

Fibrinolysis initiates when plasminogen activators convert plasminogen to plasmin, which then degrades fibrin into soluble fragments. Blood contains two immunologically and functionally distinct plasminogen activators, t-PA and u-PA. Whereas t-PA mediates intravascular fibrin degradation, u-PA binds to a specific u-PA receptor

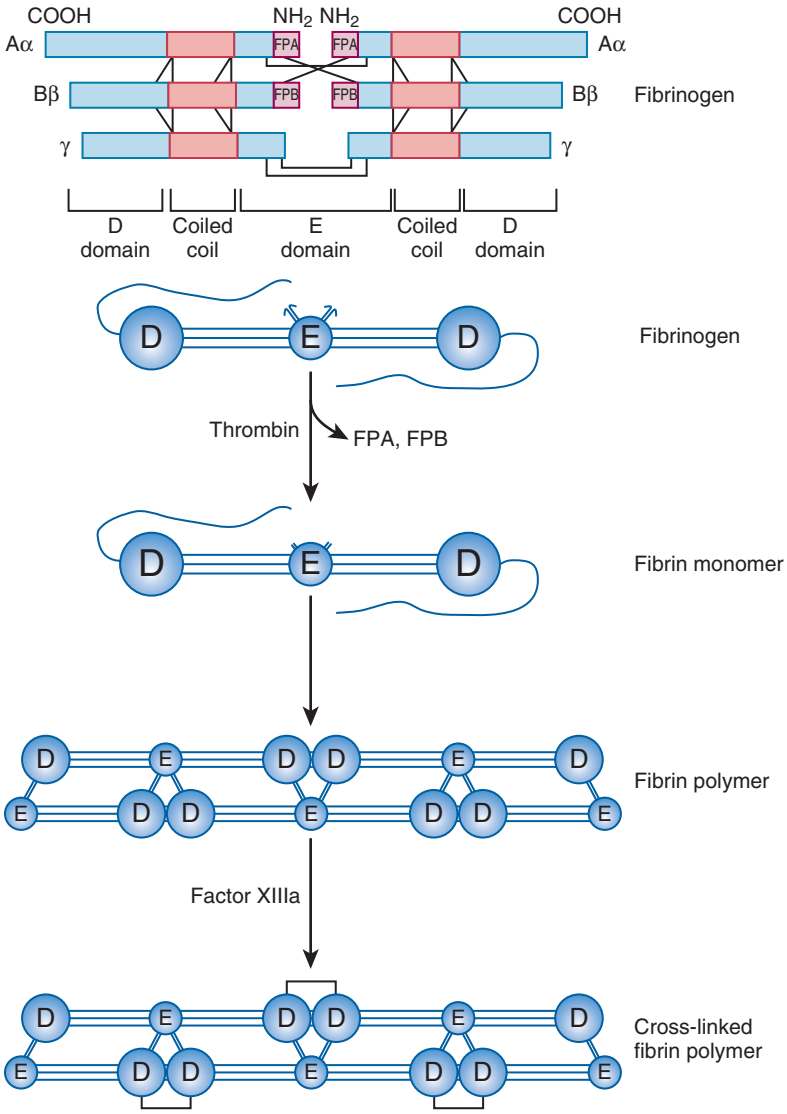

Figure 124-5 FIBRINOGEN STRUCTURE AND CONVERSION OF FIBRINOGEN TO FIBRIN. A dimeric molecule, each half of fibrinogen is composed of three polypeptide chains—the Aα, Bβ, and γ chains. Numerous disulfide bonds *(lines)* covalently link the chains together and join the two halves of the fibrinogen molecule to yield a trinodular structure with a central E domain linked via the coiled coil regions to two lateral D domains. To convert fibrinogen to fibrin, thrombin cleaves specific peptide bonds at the amino (NH_2) termini of the Aα and Bβ chains of fibrinogen to release fibrinopeptide A (FPA) and fibrinopeptide B (FPB), thereby generating fibrin monomer. Fibrin monomers polymerize to generate protofibrils arranged in a half-staggered overlapping fashion. By covalently cross-linking α and γ chains of adjacent fibrin monomers, factor XIIIa stabilizes the fibrin network and renders it resistant to degradation.

(u-PAR) on the surface of cells, where it activates cell-bound plasminogen. Consequently, pericelluar proteolysis during cell migration and tissue remodeling and repair are the major functions of u-PA.[21]

Regulation of fibrinolysis occurs at two levels (see Chapter 129). PAI-1, and to a lesser extent, PAI-2, inhibit the plasminogen activators, and α_2-antiplasmin inhibits plasmin. Endothelial cells synthesize PAI-1, which inhibits both t-PA and u-PA, whereas monocytes and the placenta synthesize PAI-2, which specifically inhibits u-PA. Thrombin-activated fibrinolysis inhibitor (TAFI) also modulates fibrinolysis and provides a link between fibrinolysis and coagulation.[22] Whereas thrombosis can occur if there is impaired activation of the fibrinolytic system, excessive activation leads to bleeding. Therefore, a review of the mechanisms of action of t-PA, u-PA, and TAFI is worthwhile.

Mechanism of Action of Tissue Plasminogen Activator

Tissue plasminogen activator, a serine protease, contains five discrete domains: a fibronectin-like finger domain, an epidermal growth factor (EGF) domain, two kringle domains, and a protease domain. Synthesized as a single-chain polypeptide, plasmin readily converts t-PA into a two-chain form. Single- and two-chain forms of t-PA convert plasminogen to plasmin. Native Glu-plasminogen is a single-chain polypeptide with a Glu residue at its amino-terminus. Plasmin cleavage at the amino-terminus generates lysine–plasminogen, a truncated form with a Lys residue at its new amino terminus.[21] t-PA cleaves a single peptide bond to convert single-chain glutamine- or lysine–plasminogen into two-chain plasmin composed of a heavy chain containing five kringle domains and a light chain containing the catalytic domain. Because its open conformation exposes the t-PA cleavage site, lysine–plasminogen is a better substrate than glutamic acid–plasminogen, which assumes a circular conformation that renders this bond less accessible.

Tissue plasminogen activator has little enzymatic activity in the absence of fibrin, but its activity increases by at least three orders of magnitude when fibrin is present. This increase in activity reflects the capacity of fibrin to serve as a template that binds t-PA and plasminogen and promotes their interaction. Whereas t-PA binds to fibrin via its finger and second kringle domains, plasminogen binds fibrin via its kringle domains. Kringle domains are loop-like structures that bind Lys residues on fibrin. As fibrin undergoes degradation, more Lys residues are exposed, which provide additional binding sites for t-PA and plasminogen. Consequently, degraded fibrin stimulates t-PA activation of plasminogen more than intact fibrin.

α_2-Antiplasmin rapidly inhibits circulating plasmin by docking to its first kringle domain and then inhibiting the active site.[21] Because plasmin binds to fibrin via its kringle domains, plasmin generated on the fibrin surface resists inhibition by α_2-antiplasmin. This phenomenon endows fibrin-bound plasmin with the capacity to degrade fibrin. Factor XIIIa cross-links small amounts of α_2-antiplasmin onto fibrin, which prevents premature fibrinolysis.[18]

Similar to fibrin, annexin II on endothelial cells binds t-PA and plasminogen and promotes their interaction. Cell-surface gangliosides and α-enolase also may bind plasminogen and promote its activation by altering its conformation into the more readily activated open form. Plasminogen binds to endothelial cells via its kringle domains. Lipoprotein a, which also possesses kringle domains, impairs cell-based fibrinolysis by competing with plasminogen for cell-surface binding. This phenomenon may explain the association between elevated lipoprotein a levels and atherosclerosis.

Mechanism of Action of Urokinase-Type Plasminogen Activator

Synthesized as a single-chain polypeptide, single-chain u-PA (scu-PA) has minimal enzymatic activity. Plasmin converts scu-PA into a two-chain form that is enzymatically active and capable of binding u-PAR, the u-PA receptor on cell surfaces. Further cleavage at the amino-terminus of two-chain u-PA yields a truncated, lower-molecular-weight form that lacks the u-PAR binding domain.

Two-chain forms of u-PA readily convert plasminogen to plasmin in the absence or presence of fibrin.[21] In contrast, scu-PA does not activate plasminogen in the absence of fibrin, but it can activate fibrin-bound plasminogen because plasminogen adopts a more open and readily activatable conformation when immobilized on fibrin. Similar to the higher-molecular-weight form of two-chain u-PA, scu-PA binds to cell surface u-PAR, where plasmin can activate it. Many tumor cells elaborate u-PA and express u-PAR on their surfaces. Plasmin generated on these cells endows them with the capacity for metastasis.

Mechanism of Action of TAFI

Thrombin-activated fibrinolysis inhibitor, a procarboxpeptidase B–like molecule synthesized in the liver, circulates in blood in a latent form where thrombin bound to thrombomodulin can activate it (see Chapters 128 and 129). Unless bound to thrombomodulin, thrombin activates TAFI inefficiently.[22] TAFIa attenuates fibrinolysis by cleaving lysine residues from the carboxy termini of chains of degrading fibrin, thereby removing binding sites for plasminogen, plasmin, and t-PA. TAFI links fibrinolysis to coagulation because the thrombin–thrombomodulin complex not only activates TAFI, which attenuates fibrinolysis, but also activates protein C, which mutes thrombin generation.

Activated TAFI (TAFIa) has a short half-life in plasma because the enzyme is unstable.[22] Genetic polymorphisms can result in synthesis of more stable forms of TAFIa. Persistent attenuation of fibrinolysis by these variant forms of TAFIa may render patients susceptible to thrombosis.

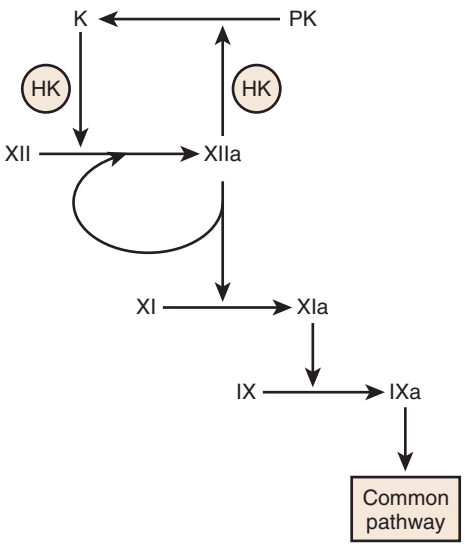

Figure 124-6 CONTACT SYSTEM. Factor XII (XII) is activated by contact with negatively charged surfaces. XIIa converts prekallikrein (PK) to kallikrein (K) and can feed back to activate more XII. Likewise, XIIa also can feed back to amplify its own generation. About 75% of circulating PK is bound to high-molecular-weight kininogen (HK), which localizes it to anionic surfaces and promotes PK activation. XIIa propagates clotting by activating XI, which then activates IX. The resultant IXa assembles into the intrinsic tenase complex, which activates X to initiate the common pathway of coagulation.

DISORDERS OF HEMOSTASIS OR THROMBOSIS

A physiologic host defense mechanism, hemostasis focuses on arrest of bleeding by forming hemostatic plugs composed of platelets and fibrin at sites of vessel injury. In contrast, thrombosis reflects a pathologic process associated with intravascular thrombi that fill the lumens of arteries or veins.

Hemostatic Disorders

Bleeding can occur if there is abnormal platelet plug formation or reduced thrombin generation and subsequent fibrin clot formation at the site of vascular injury; disorders of primary and secondary hemostasis, respectively. Bleeding also can occur if the platelet or fibrin clot is prematurely degraded because of excessive fibrinolysis; a disorder of tertiary hemostasis, the features distinguishing disorders of primary, secondary, and tertiary hemostasis are outlined in Table 124-1. Hemorrhagic disorders can be inherited or acquired, and the clinical and laboratory evaluation of such disorders is detailed in Chapters 130 and 131, respectively.

Disorders of Primary Hemostasis

Platelet plug formation, the first step in the arrest of bleeding at sites of injury, requires three key components (1) an adequate number of functional platelets; (2) vWF, the molecular glue that mediates platelet adhesion to the damaged vessel wall even in the face of high shear; and (3) a normal blood vessel that constricts in response to injury (Table 124-2). Because the platelet plug provides the first line of defense against bleeding, patients with disorders of primary hemostasis often present with immediate bleeding after injury and petechiae, pinpoint hemorrhages, may be noted. In addition to skin bleeding,

Table 124-1 Comparison of the Features of Disorders of Primary, Secondary, or Tertiary Hemostasis

Features	Primary	Secondary	Tertiary
Components involved	Platelets, vWF, and vessel wall	Coagulation	Fibrinolytic factors
Site of bleeding	Skin and mucocutaneous and soft tissues	Muscles, joints, and deep tissues	Wounds and genitourinary tract
Physical findings	Petechiae and ecchymoses	Hematomas and hemarthroses	Hematuria and menorrhagia
Timing of bleeding	Immediate	Delayed	Delayed
Inheritance	Autosomal dominant	Autosomal or X-linked recessive	Autosomal recessive

vWF, von Willebrand Factor

Table 124-2 Disorders of Primary Hemostasis

Components Affected	Causes
Platelets	Quantitative or qualitative platelet disorders
vWF	Inherited or acquired deficiency or dysfunction of vWF
Vessel wall	Vasculitis or abnormalities of connective tissue supporting the vasculature

vWF, von Willebrand factor

Table 124-3 Disorders of Secondary Hemostasis

Component Affected	Causes
Coagulation factors	Congenital deficiency, autoantibodies, increased consumption, or drugs that attenuate thrombin generation or thrombin activity
Fibrinogen	Decreased production; increased consumption or synthesis of an abnormal protein
	Impaired fibrin polymerization because of fibrin(ogen) degradation products or paraproteins
Fibrin cross-linking	Congenital or acquired factor XIII deficiency

mucocutaneous bleeding, which may manifest as epistaxis, bleeding gums, or hematochezia, is common as is excessive menstrual bleeding in women (see Chapter 130).

Disorders of primary hemostasis may be inherited or acquired.[23] Thrombocytopenia or congenital or acquired disorders of platelet function are common causes of bleeding. Thrombocytopenia can be the result of decreased production, which can occur because of failure, infiltration, or fibrosis of the bone marrow (see Chapters 27 and 28); increased platelet destruction; or abnormal distribution because of platelet pooling in the spleen (see Chapter 134). Increased destruction of platelets can occur via immune mechanisms, such as immune thrombocytopenic purpura (ITP), alloimmune thrombocytopenia, posttransfusion purpura and drug-induced thrombocytopenia (see Chapter 133), or nonimmune mechanisms, which include microangiopathic disorders, such as thrombotic thrombocytopenic purpura and hemolytic uremic syndrome (see Chapter 136), as well as consumption because of activation of coagulation, such as occurs with disseminated intravascular coagulation (see Chapter 141).

Platelet function disorders include disorders of (1) platelet adhesion, such as von Willebrand disease (see Chapter 140) and Bernard-Soulier syndrome (see Chapter 127); (2) thromboxane synthesis; (3) secretion, such as alpha or dense granule deficiency or aspirin-like secretion defects; (4) aggregation, such as Glanzmann thrombasthenia (see Chapter 127); or (5) procoagulant activity (Scott syndrome) in which the platelets fail to support clotting factor complex assembly (see Chapter 128). Acquired disorders of platelet function can occur in patients taking drugs that impair platelet function, such as aspirin or nonsteroidal antiinflammatory drugs, or in patients with uremia, paraproteins, or myelodysplastic or myeloproliferative disorders (see Chapter 132).

Bleeding can also occur with inflammation or malformations of the blood vessels or abnormalities of the connective tissue supporting the blood vessels. Inflammatory disorders include Henoch-Schonlein purpura (see Chapter 152) and the vasculitis that occurs with paraproteins or cryoglobulins or in patients with systemic lupus erythematosus or other immune disorders.[24] Hereditary hemorrhagic telangiectasia is an inherited disorder associated with malformations of the capillaries. Telangiectatic vessels can often be seen in the oral and nasal cavities of patients with this disorder and bleeding episodes, primarily from the nose and gastrointestinal tract, are common. Abnormalities of the connective tissue matrix supporting the blood vessels include Marfan syndrome, Ehlers-Danlos syndrome, and pseudoxanthoma elasticum.[25] Patients with these disorders frequently report easy bruising.

Disorders of Secondary Hemostasis

Secondary hemostasis depends on rapid generation of sufficient amounts of thrombin to generate a fibrin mesh that not only consolidates the platelet aggregates that form at sites of vascular injury but is also stable enough to provide a barrier that prevents leakage of blood from the damaged blood vessel.[18] Secondary hemostasis can be compromised by (1) impaired thrombin generation because of congenital or acquired deficiencies of coagulation factors or cofactors or intake of drugs that inhibit one or more steps in the coagulation pathways, (2) congenital or acquired fibrinogen deficiency or dysfunction, or (3) impaired cross-linking of fibrinogen because of congenital or acquired deficiency of factor XIII (Table 124-3).

Examples of inherited deficiencies of coagulation factors include hemophilia A and B, deficiencies of factor VIII and factor IX, respectively (see Chapter 137). Because of redundancy in the coagulation system, only patients with a factor VIII or factor IX level less than 1% have severe disease characterized by spontaneous bleeding or bleeding with minimal trauma. Whereas those with factor levels between 1% and 5% have an intermediate phenotype, patients with factor VIII or IX levels above 5% usually have mild disease and bleed only with trauma or surgery. The frequency of bleeding episodes in patients with severe hemophilia can be reduced by prophylactic administration of the appropriate factor concentrate; such treatment is also administered to those with hemophilia who have overt bleeding or in preparation for surgery or other major interventions. Management of hemophilia becomes more complicated if patients develop inhibitory antibodies that attenuate or abolish the activity of the infused factor (see Chapter 138). Congenital deficiencies of prothrombin (factor II), factors V, VII, X, or XI (hemophilia C) or fibrinogen are less common causes of bleeding (see Chapter 139). In contrast, deficiencies of components of the contact pathway (factor XII, high-molecular-weight kininogen, and prekallikrein) are not associated with bleeding. The clinical and laboratory evaluation of such patients are detailed in Chapters 130 and 131, respectively, and their treatment is outlined in Chapter 116.

Acquired deficiencies of coagulation factors can result from decreased synthesis because of severe liver disease, vitamin K deficiency or intake of drugs that interfere with vitamin K metabolism, consumption because of excessive activation of coagulation (e.g., disseminated intravascular coagulation; see Chapter 141), or accelerated clearance caused by adsorption by paraproteins or amyloid (see Chapters 85 and 86) or caused by autoantibodies that shorten the half-life or attenuate or abolish clotting factor activity.

Congenital disorders of fibrinogen include absence or low levels of fibrinogen (afibrinogenemia and hypofibrinogenemia, respectively) or synthesis of a dysfunctional protein (dysfibrinogenemia). Acquired disorders of fibrinogen include decreased synthesis or production of an abnormal fibrinogen and increased fibrinogen consumption or the presence of inhibitors that interfere with fibrin polymerization, such as paraproteins or autoantibodies, particularly in patients with systemic lupus erythematosus or other immune disorders or elevated levels of fibrin(ogen) degradation products.

Stabilization of fibrin requires cross-linking of the α and γ chains of adjacent fibrin monomers to yield a polymer that is resistant to premature breakdown. Factor XIIIa, a transglutaminase, performs this function by catalyzing the condensation of lysine residues on one chain with glutamic acid residues on another chain.[26] Congenital or acquired deficiency of factor XIII can impair cross-linking, resulting in bleeding. The hallmarks of severe factor XIII deficiency include umbilical stump bleeding in the neonatal period (see Chapter 152); intracranial hemorrhage with little or no trauma; recurrent soft tissue hemorrhages; and, in women, recurrent spontaneous miscarriages.

Table 124-4 Disorders of Tertiary Hemostasis

Component Affected	Causes
Plasminogen activators	Increased t-PA or u-PA release in the GU tract or other tissues
Plasmin	Deficiency of PAI-1 or α_2-antiplasmin, resulting in an increased plasmin concentration
Plasminogen activation	Enhanced plasminogen activation secondary to activation of coagulation by procoagulants, such as cancer cells, artificial surfaces, or snake venoms

GU, Genitourinary; *PAI-1,* plasminogen activator inhibitor 1; *t-PA,* tissue plasminogen activator; *u-PA,* urokinase-type plasminogen activator.

Disorders of Tertiary Hemostasis

Tertiary hemostasis depends on the generation of plasmin, which degrades fibrin and restores blood flow in damaged vessels. Premature lysis of fibrin in hemostatic plugs can lead to bleeding; this can occur systemically or can be localized (Table 124-4). Systemic fibrinolysis that occurs in the absence of activation of coagulation, so-called primary hyperfibrinolysis, is rare but can occur with inherited deficiency of PAI-1 or α_2-antiplasmin, the inhibitors of the plasminogen activators and plasmin, respectively; advanced liver disease; and some snake bites. More commonly, systemic hyperfibrinolysis is secondary to activation of coagulation by procoagulants such as tissue factor (e.g., in patients with metastatic cancer) or artificial surfaces (e.g., in cardiopulmonary bypass surgery or with cardiac assist devices). Examples of localized hyperfibrinolysis include menorrhagia or hematuria after prostatectomy triggered by excessive plasmin generation induced by the high concentrations of t-PA and u-PA in the uterus and genitourinary tract, respectively.

Thrombotic Disorders

Thrombosis may occur in arteries, in the chambers of the heart, or in the veins. Factors contributing to thrombosis in these sites include endothelial injury or activation, reduced blood flow, and hypercoagulability of the blood, the so-called Virchow triad.

Arterial Thrombosis

Most arterial thrombi occur on top of disrupted atherosclerotic plaques. Plaques with a thin fibrous cap and a lipid-rich core are most prone to disruption. Erosion or rupture of the fibrous cap exposes thrombogenic material in the lipid-rich core to the blood and triggers platelet activation and thrombin generation. The extent of plaque disruption and the content of thrombogenic material in the plaque determine the consequences of the event regardless of whether it occurs in the cerebral circulation (see Chapter 147), the coronary circulation (see Chapter 148), or the major arteries of the legs (see Chapter 150), but host factors also contribute. Breakdown of regulatory mechanisms that limit platelet activation and inhibit coagulation can augment thrombosis at sites of plaque disruption.

Decreased production of nitric oxide and prostacyclin by diseased endothelial cells can trigger vasoconstriction and platelet activation. Proinflammatory cytokines lower thrombomodulin expression by endothelial cells, which promotes thrombin generation, and stimulate PAI-1 expression, which inhibits fibrinolysis.

Products of blood coagulation contribute to atherogenesis, as well as to its complications (see Chapter 146). Microscopic erosions in the vessel wall trigger the formation of tiny platelet-rich thrombi.[27] Activated platelets release PDGF and TGFβ, which promote a fibrotic response. Thrombin generated at the site of injury not only activates platelets and converts fibrinogen to fibrin but also activates PAR-1 on smooth muscle cells and induces their proliferation, migration, and elaboration of extracellular matrix. Incorporation of thrombi into plaques promotes plaque growth, and decreased endothelial cell production of heparan sulfate—which normally limits smooth-muscle proliferation—contributes to plaque expansion.[27] The multiple links between atherosclerosis and thrombosis have prompted the term atherothrombosis (see Chapter 146).

Intracardiac Thrombosis

Thrombi can form in the left ventricle after transmural myocardial infarction or with an aneurysm or dyskinetic ventricle or in the left atrial appendage, particularly in patients with atrial fibrillation (see Chapter 149). Damage to the endothelium after myocardial infarction and abnormal blood flow are the major triggers for left ventricular thrombus formation. With rapid atrial fibrillation, there also is stasis and turbulent blood flow in the left atrial appendage, which is a long, blind-ended trabeculated pouch.[28] This may lead to localized activation of endothelial cells and subsequent loss of their anticoagulant phenotype, a process amplified by adhesion of leukocytes and subsequent elaboration of proinflammatory cytokines. The generation of thrombin creates a local hypercoagulable state that likely promotes thrombus formation on the abnormal endothelium. Embolization of these thrombi to the brain is a common cause of ischemic stroke and is the major cause of mortality and morbidity in patients with atrial fibrillation.

Venous Thrombosis

The causes of venous thrombosis include those associated with hypercoagulability, which can be genetic or acquired, and the mainly acquired risk factors, such as advanced age, obesity, or cancer, which are associated with immobility (see Chapters 142 and 144). Inherited hypercoagulable states and these acquired risk factors combine to establish the intrinsic risk of thrombosis for each individual.[2] Superimposed triggering factors, such as surgery, pregnancy, or hormonal therapy, modify this risk, and thrombosis occurs when the combination of genetic, acquired, and triggering forces exceed a critical threshold.[29]

Some acquired or triggering factors entail a higher risk than others. For example, major orthopedic surgery, neurosurgery, multiple trauma, and metastatic cancer (particularly adenocarcinoma) are associated with the highest risk; prolonged bed rest, antiphospholipid antibodies (see Chapter 143), and the puerperium period are associated with an intermediate risk; and pregnancy, obesity, long-distance travel, and the use of oral contraceptives or hormonal replacement therapy are mild risk factors. Up to half of patients who present with venous thromboembolism before the age of 45 years have inherited hypercoagulable disorders—so-called thrombophilia (see Chapter 142)—particularly those whose event occurred in the absence of risk factors or with minimal provocation, such as after minor trauma or a long-haul flight or with estrogen use.[30]

CHAPTER 125

THE BLOOD VESSEL WALL

Aly Karsan and John M. Harlan

The vasculature plays a major role in conveying and distributing hematopoietic cells, nutrients, gases, metabolites, and various chemical mediators.[1] The interior of the vessel wall is lined by the endothelium, comprising more than 1012 endothelial cells, covering a surface of approximately 500 m^2 and weighing approximately 1 kg in total.[2,3] The endothelium forms a continuous monolayer at the interface between blood and tissue. Thus it contributes significantly to sensing and transducing of signals between blood and tissue, trafficking of hematopoietic cells, and maintenance of a nonthrombogenic surface permitting flow of blood. Normally quiescent with cell turnover measured on the order of years, endothelial cells have a remarkable capacity to proliferate and vascularize tissues in physiologic (menstrual cycle) and pathologic (tumorigenesis, diabetic retinopathy) situations.[4] The endothelium is critical for initiating and potentiating the inflammatory response. The pathogenesis of several disorders, such as atherosclerosis, hypertension, diabetic angiopathy, and microangiopathic hemolytic anemias, involves dysfunction of the endothelial lining. The complexity and the vast array of its functional responses have led to the description of the endothelium as a distributed organ.[5] This chapter provides a conceptual framework of the structure and development of the vessel wall and the physiologic functions of the endothelium as it relates to the hematopoietic system.

STRUCTURE OF THE VESSEL WALL

The circulatory system has traditionally been divided into the macrovasculature (vessels >100 μm in diameter) and the microvasculature.[6] The arterial system transports blood to tissues, resists changes in blood pressure proximally, and regulates blood flow distally. Veins return blood to the heart and act as capacitance vessels because they contain approximately 70% of the total blood volume. Venules with luminal diameters less than 50 μm are structurally similar to capillaries.[6] Capillaries and microvessels in general are particularly important in the exchange of gases, macromolecules, and cells between blood and tissue. Although large vessels play an important role in maintaining vascular tone, a significant proportion of peripheral resistance arises from the capillaries.[7] Capillary endothelial cells also have a metabolic role, as in the conversion of angiotensin and hydrolysis of lipoproteins. Finally, sprouting of new vessels is initiated in the microvasculature.

Macrovasculature

Large vessels are composed of three layers: intima, media, and adventitia.[6,8] The intima comprises the endothelium and the subendothelium. The endothelial cells of large vessels contain a distinct rod-shaped organelle, measuring approximately 3 μm × 0.1 μm, called the Weibel-Palade body.[9] Ultrastructural studies indicate the presence of a single membrane around the Weibel-Palade body with tubular structures within. This organelle contains von Willebrand factor (vWF), and P-selectin has been reported to be present on the surrounding membrane.[10-12] The abluminal face of the endothelium rests on a basement membrane, which supports the endothelial cell and can act as a secondary barrier against the extravasation of blood.[2] The subendothelial matrix contains occasional smooth muscle cells and scattered macrophages. Both smooth muscle cells and endothelial cells contribute to the extracellular matrix (ECM) of the intima.[13,14] In large vessels, the media is separated from the intima by a layer of elastin, the internal elastic lamina. The medial layer is composed primarily of concentric layers of smooth muscle cells and their secreted matrix, which is a complex mix of glycoproteins and proteoglycans. This layer is responsible for the structural integrity of the wall and for maintaining vascular tone. Mutations of the fibrillin-1 gene, a microfilament protein in elastic fibers, result in disruption of the media in Marfan syndrome.[12] Defects of type III collagen can cause aortic rupture in patients with Ehlers-Danlos syndrome type IV.[14] An attenuated band of elastic fibers, the external elastic lamina, separates the adventitia from the media. The adventitia is composed of loose connective tissue, and the outer portion of the media contains small nerves and nutritive blood vessels, the vasa vasorum. The external limit of the adventitial layer is loosely defined and becomes continuous with the surrounding connective tissue of the organ.[6,8]

Microvasculature

Capillaries and postcapillary venules are composed of two cell types: endothelial cells and pericytes.[15] Pericytes and endothelial cells are invested with a basement membrane and, depending on the vascular bed, variable amounts of matrix separate the two cell types. Both cell types contribute to secretion of basement membrane proteins. Long pericyte processes extend over the abluminal surface of the endothelial cell, and reciprocal extensions of the endothelial cell make contact with the pericyte. Pericytes and endothelial cells communicate via gap junctions.[16] A variety of functions has been ascribed to the pericyte, including[15,17,18] (1) a contractile function, which regulates blood flow; (2) multipotential capabilities resulting in differentiation to adipocytes, osteoblasts, phagocytes, and smooth muscle cells; and (3) regulation of capillary growth. The best evidence probably exists for the last function. In animal models[19,20] and human disease (diabetic microangiopathy, hemangiomata),[21] a lack of pericytes is associated with microaneurysms and disordered microvasculature. In addition, there is a temporal correlation between pericyte contact and cessation of vessel growth in wound healing,[22] and pericyte contact suppresses endothelial cell migration and proliferation in vitro.[15]

Endothelial Structure and Function

In contrast to circulating blood cells and vascular smooth muscle cells but similar to epithelial cells, the endothelium exhibits polarity manifested by the asymmetric distribution of cell surface glycoproteins and by the unidirectional secretion of some ECM proteins and chemical mediators.[23,24] Although in cultured endothelial cells, an apical–basal polarity is established before confluence, intercellular junctions may have a role in maintaining the asymmetry in vivo.[23,25]

Four types of intercellular junctions between adjacent endothelial cells have been described[25,26]: tight junctions, gap junctions, adherens junctions, and syndesmos. Their distribution varies along the vascular

tree, with tight junctions occurring more frequently in the larger arteries and brain vasculature, correlating with a more stringent requirement for permeability control. The molecular structure of endothelial tight junctions is similar to that of epithelial cells, consisting of a network of fibrils, with the integral membrane components composed of occludin, claudin-5, and junctional adhesion molecules (JAMs), which associate with various structural and signaling proteins on the cytoplasmic face.[27] The distribution of gap junctions tends to follow that of tight junctions. Connexin 37, connexin 40, and connexin 43 are gap junction proteins that have been detected in endothelial cells. Gap junctions mediate communication between adjacent endothelial cells and between endothelial cells and pericytes or smooth muscle cells; they also may contribute to the endothelial barrier. Adherens junctions are formed by transmembrane glycoproteins called cadherins, which make the link between cell-to-cell contacts and the cytoskeleton. Several different types of cadherins are expressed in endothelial cells. The endothelial-specific cadherin vascular endothelial cadherin (VE-cadherin [cadherin-5]) is expressed on virtually all types of endothelium.[26] Similar to other cadherins, VE-cadherin forms homotypic contacts with VE-cadherin on adjacent cells. Within the cell, VE-cadherin complexes with catenins, which, through other proteins, contact the actin cytoskeleton. Homotypic engagement of VE-cadherin results in density-dependent inhibition of endothelial proliferation, which appears to be mediated by association of vascular endothelial growth factor receptor 2 (VEGFR-2) with VE-cadherin, thereby sequestering VEGFR-2 at the membrane and preventing its internalization into signaling compartments.[28] The structure of the fourth type of junction, the syndesmos, is not well elucidated.

Other membrane proteins that are located at interendothelial junctions include platelet endothelial cell adhesion molecule 1 (PECAM-1), which may be important in directing the formation of junctions, and the integrins (particularly $\alpha 2\beta 1$ and $\alpha 5\beta 1$).[29] In addition to the functions listed previously, intercellular contacts are important in maintaining cell survival.[30]

On the luminal side, endothelium is exposed to blood elements and, under pathologic conditions, to circulating molecules such as cytokines and bacterial products. Engagement of endothelial receptors by these humoral factors activates a well-described series of responses. including the recruitment and transmigration of leukocytes and changes in endothelial cell coagulant activity (see The Endothelium as a Nonthrombogenic Surface). Biomechanical forces resulting from pulsatile blood flow have been shown to mediate striking changes in endothelial morphology and metabolism. Vessels must withstand three types of physical forces: radial distension (tension), longitudinal stretch, and tangential shear stress. In response to flow (shear stress), endothelial cells reorganize their cytoskeletal architecture, rearrange focal contacts at the basal surface, and align in the direction of flow.[31-33] Some endothelial cell responses following exposure to physical forces occur within seconds, such as activation of potassium channels and increased release of nitric oxide (NO), resulting in vasodilation. Other endothelial cell responses to flow are related to changes in gene expression and occur after a delay of a few hours. Elements in the promoters of various adhesion molecule and growth factor genes have been shown to contain sequences that respond to shear stress (in a positive or negative fashion) and have been referred to as the shear stress response element.[31-33]

Endothelial cells vectorially secrete certain ECM proteins to the abluminal face. The matrix molecules that are secreted by endothelium include several types of collagen, elastin, fibronectin, laminins, and proteoglycans (e.g., heparan sulfate, dermatan sulfate). The exact composition of the subendothelium varies with location in the vascular tree, age, and disease states.[2,14,34] Endothelial cells bind to the ECM via heterodimeric cell surface glycoproteins—the integrins—which link and integrate matrix proteins to the cytoskeleton at sites referred to as focal contacts.[35] The integrins detected in resting endothelium include $\alpha 6\beta 1$, $\alpha 5\beta 1$, $\alpha 2\beta 1$, and $\alpha v\beta 3$.[36] Interestingly, endothelial cells express integrins on luminal as well as abluminal surfaces.[36] The ECM serves several important functions: (1) it serves as a barrier to macromolecules in the event of disruption of the endothelium; (2) it sequesters growth factors and mediates their high-affinity binding to endothelial cells (e.g., heparan sulfate binds to fibroblast growth factor [FGF]); and (3) it acts as a counterstructure for the binding of endothelial cell integrins.[14,34,37] This binding of endothelial cells to the ECM serves at least four purposes: (1) Whereas certain matrix molecules provide a physical scaffold, others act as haptotactic agents, inducing endothelial cells to migrate.[14] (2) Clustering of integrins at focal adhesion contacts by certain matrix molecules can transduce survival or differentiation signals by causing phosphorylation of various proteins and lipids.[37] Whereas fibronectin and vitronectin provide survival signals, laminins appear to signal differentiation.[38-40] (3) By maintaining cell shape, integrin-mediated cell spreading provides an antiapoptotic signal independent of direct integrin-initiated signal transduction.[41] (4) By anchoring the cell, the matrix provides a mechanism whereby blood flow at the luminal surface of the endothelium creates shear stress, which also transmits signals to cells.[31]

Endothelial Heterogeneity

Despite their common features, quiescent endothelial cells in vivo represent a widely heterogeneous population, with their phenotype depending on vessel caliber and location. Exposure to different physical forces (e.g., arteries vs. veins) and the different functions served by vessels of different caliber are reflected in different endothelial phenotypes.[42] However, study of the molecular basis of the heterogeneity of these different populations is just beginning. Experiments using serial analysis of gene expression and in vivo delivery of phage display peptide libraries have revealed organ- and tumor vasculature–specific molecules that will help to elucidate the molecular basis of endothelial heterogeneity.[43-45] Within the microvasculature is a structural heterogeneity of capillaries, depending on the organ supplied. Even within a single organ, endothelial cells exhibit different phenotypes, depending on their functional role. When microvessels from different organs are harvested and cultured in vitro, they lose some of their distinctive characteristics with progressive passaging. Some specialization of the different endothelial cells can be retained if they are cocultured with cells or matrix from the organ from which they are derived. Thus matrix proteins, soluble factors from the organ, or heterotypic contacts with parenchymal cells or pericyte or smooth muscle cells are believed to be important factors in specifying endothelial cell phenotype.[46] Conversely, emerging evidence indicates that endothelial cells in turn provide instructive morphogenic cues during organogenesis and in adults.[47] Specific examples of microvessels found in hematopoietic tissues are discussed in the following sections.

High Endothelial Venules

Lymphocyte migration into secondary lymphoid sites, such as lymph nodes, Peyer patches, and chronically inflamed nonlymphoid tissues, occurs at specialized postcapillary venules.[48] The endothelial cells of these venules exhibit a plump or cuboidal morphology (hence the name high endothelial venule), display intense biosynthetic activity, and are encircled by a continuous basal lamina. They secrete a thick glycocalyx of which a proportion is glycosylation-dependent cell adhesion molecule 1, a ligand for L-selectin.[49] CD34 is another high endothelial venule "addressin" on peripheral lymph node endothelial cells. Endothelium of mesenteric lymph nodes and Peyer patches express mucosal addressin cellular adhesion molecule 1 (MAdCAM-1) as a ligand for L-selectin and $\alpha 4\beta 7$ integrin. Expression of these different addressins may recruit specific subpopulations of lymphocytes to different lymphoid tissues (i.e., they facilitate the "homing" of lymphocytes). Several other proteins, including the chemokine receptor DARC (Duffy antigen receptor for chemokines) and the antiadhesive matrix protein Hevin, have been identified as being preferentially expressed by the high endothelial venule.[50] Tight junctions are present at intermittent spots, and extensive overlap between the membranes of adjacent cells prevents macromolecules from interendothelial transit. However, when lymphoid cells transit to the high

endothelial venule, there is a temporary breach in the barrier.[49] Evidence suggests that the high endothelial venule not only plays a critical role in homing and recruitment of immune cells but also can influence the outcome of the immune response.[51]

Bone Marrow Sinuses

Much less is known about the bone marrow (BM) sinuses than about the high endothelial venule. The BM sinus endothelial cell is flat, in contrast to that of the high endothelial venule, and the basal lamina is discontinuous. It has been suggested that hematopoietic cells traverse pores present at attenuated areas of the endothelium rather than moving by an interendothelial route.[52] Clearly, the BM sinus endothelial cell is specialized given the regulated egress of cells from the BM. For example, if a red blood cell (RBC) that still is nucleated begins to enter the circulation, the body of the cell is allowed to cross and is released as a reticulocyte, while the nucleus is retained extravascularly. The adventitial reticular cell (similar to a pericyte) is also thought to play an important role in controlling hematopoietic cell egress.[53] Stromal cell–derived factor 1 (SDF-1, also called CXCL12) and chemokine receptor CXCR4 interactions are essential for stem cell homing, mobilization, and transendothelial migration into the BM.[54,55] SDF-1 activates the integrins lymphocyte function-associated antigen 1 (LFA-1 [αLβ2]), very late antigen 4 (VLA-4 [α4β1]), and very late antigen 5 (VLA-5 [α5β1]). Whereas vascular cell adhesion molecule 1 (VCAM-1), which is expressed on BM endothelial cells (and spleen endothelial cells in the mouse), appears to be the major BM addressin for hematopoietic progenitor cells expressing VLA-4, intercellular adhesion molecule 1 (ICAM-1) binds LFA-1.[55,56] Endothelial selectins also have been implicated in promoting hematopoietic progenitor homing to the BM.[57] Factors such as CD44, cytoskeletal rearrangement, and matrix metalloproteinases (MMPs) are other key players in the homing process related to the endothelium.[55] The BM endothelium also is involved in regulating hematopoiesis (see Relationship Between Vascular Development and Hematopoiesis).

VASCULAR DEVELOPMENT AND DIFFERENTIATION

The human embryo develops a vascular system by the third week, when its nutritional needs are no longer met by diffusion.[58] Vascular development proceeds in several ways. Vasculogenesis is the process whereby blood vessels form de novo from the differentiation of mesodermal precursors. Angiogenesis is the outgrowth of new capillaries from preexisting vessels and is thought to be the major mode of new vessel development in the adult. Arteriogenesis, or collateral development, is the rapid enlargement of preexisting collateral arterioles after occlusion of a supply artery. Lymphangiogenesis is the development of lymphatic vessels, which are required for transportation of extravasated lymph and lymphoid cells. Finally, in some neoplasms, tumor cells rather than endothelial cells form vascular channels or a portion of some vessels, a process termed *vasculogenic mimicry*.[59] A similar nonendothelial cell lining of vascular channels can be created by placental cytotrophoblasts forming hybrid fetal–maternal vessels in the endometrium.[59]

Vasculogenesis

Vasculogenesis in the yolk sac proceeds initially by the differentiation of mesodermal cells into angioblasts.[60] Angioblasts are vascular cells that express some, but not all, endothelial markers. These cells arise from mesodermal cells resting on the endoderm (splanchnopleuric mesoderm) but not from the mesoderm adjacent to the ectoderm (somatopleuric mesoderm). Thus it is believed that whereas the endoderm positively regulates vascular development, the ectoderm negatively regulates vasculogenesis. Organs that are primarily of ectodermal origin (e.g., brain and kidney) are vascularized by angiogenesis and not by vasculogenesis. The mesodermal cells migrating outward from the endoderm form primitive structures termed *blood islands*. Whereas the cells at the center of the blood island are hematopoietic precursors, those arranged peripherally are angioblastic precursors. Vasculogenesis within the embryo begins shortly after that in the yolk sac, again in close association with endoderm.[61] However, except for a region on the ventral aspect of the embryonic aorta, intraembryonic vascular development occurs in solitary angioblasts rather than blood islands. Angioblasts differentiate in situ and form primary capillary plexuses with lumens, or they migrate and fuse with other angioblasts or capillaries. Fusion of angioblasts or blood islands results in the formation of a capillary plexus that undergoes extensive remodeling over the developmental period.[60]

Vasculogenesis in the Adult

Although initially said to occur primarily in the embryo, vasculogenesis may also play a role in promoting vascular development in adults. The identification of circulating BM-derived vascular precursors and the demonstration that these precursors can integrate into the vasculature at sites of angiogenesis describe an adult form of de novo vessel development.[62] Two distinct BM-derived precursors with the ability to differentiate into vascular cells have been identified: (1) accumulating evidence points to a single precursor, the hemangioblast, which can differentiate into either hematopoietic or endothelial cells,[63] and (2) a multipotent nonhematopoietic adult progenitor cell, which is thought to represent a BM mesenchymal stem cell. When injected intravenously into adult mice, these mesenchymal stem cells differentiated into vascular cells, hematopoietic cells, and several epithelial cell types.[64,65] Both types of multipotential precursor populations express CD133, a cell surface marker that is lost upon further maturation.[66] However, only the hemangioblast expresses CD34. Whether mesenchymal stem cells are able to circulate and thus contribute to neovascularization outside the BM remains to be shown. Various stresses, including neoplasia, sepsis, burns, and trauma, have been suggested to induce mobilization of BM-derived endothelial precursors, which express CD133, CD34, and VEGFR-2.[66] Cytokines that reportedly induce mobilization of BM-derived endothelial precursors include VEGF-A and granulocyte macrophage colony-stimulating factor (GM-CSF).[66] The contribution of BM-derived vascular precursors to angiogenic vessels in tumors is highly variable, depending on the study, the model used, and the tumor cell type used.[67] The degree of endothelial precursor incorporation into the angiogenic vasculature is highly controversial; several groups suggest negligible, if any, involvement by distant precursors.[67] The problem arises in part from the poor definition of a circulating endothelial precursor cell. Many, if not all, of the markers used to define this rare cell population are shared with hematopoietic stem or progenitor cells, and the distinction between the endothelial and hematopoietic precursor has not been rigorously addressed in the majority of studies. More recent work has suggested that BM-derived, perivascular CD11b+ hematopoietic cells secreting angiogenic cytokines have been misidentified as endothelial precursor cells.[68,69]

Angiogenesis

In a normal adult, angiogenesis occurs primarily in the female reproductive system. However, angiogenesis is a process that has a major impact in several pathologic situations. Probably the best-known and studied example of pathologic neovascularization occurs during tumor progression. Angiogenesis also is important in chronic inflammation, ischemia, and wound healing.

Capillary sprouts from the existing microvasculature form secondary to an inciting stimulus that results in increased vascular permeability, accumulation of extravascular fibrin, and local proteolytic degradation of the basement membrane.[70-72] Endothelial cells overlying the disrupted region become "activated," change shape, and extend elongated processes into the surrounding tissue. Filopodia extending from the specialized endothelial cells at the tip of the

vascular sprout guide the migration of the nascent vessel.[73] Directed migration toward the angiogenic stimulation results in the formation of a column of endothelial cells. Just proximal to the migrating tip of the column is a region of proliferating endothelial cells. These proliferating cells cause an increase in the length of the sprout. In the region of proliferation, up to 20% of endothelial cells may enter the cell cycle. This is in marked contrast to quiescent endothelium, of which less than 0.01% of cells are cycling. Proximal to the proliferative zone, the endothelial cells undergo another shape change, adhere tightly to each other, and begin to form a lumen. Evidence suggests that endothelial lumina arise through the formation and fusion of intracellular vacuoles.[74] Secondary sprouting from the migrating tip results in a capillary plexus, and fusion of individual sprouts at their tips closes the loop and circulates blood into the vascularized area. Activated macrophages and platelets, by secreting growth factors, cytokines, proteases, and protease inhibitors, can influence all phases of the angiogenic process.[75]

The morphologic features described are characteristic of sprouting angiogenesis. *Intussusceptive microvascular growth* refers to vascular network formation by insertion of interstitial tissue columns, called tissue pillars or posts, into the vascular lumen and subsequent growth of these columns, resulting in partitioning of the vessel lumen. The mechanisms of intussusceptive angiogenesis are less well described, but hemodynamic factors appear to be involved.[76]

Recruitment of Periendothelial Cells

Whether formed by vasculogenesis or angiogenesis, maturation of new vessels requires recruitment of smooth muscle cells or pericytes to reestablish vessel integrity. Periendothelial cells provide structural support, assist in production of the ECM, provide contractile function so as to modulate vessel caliber, and maintain the cells in a quiescent state. Genetically altered mice that fail to invest their vessels with pericytes develop microaneurysms.[19] In embryos, periendothelial cells are thought to be derived from locally available mesenchymal cells as endothelial cells invade organ rudiments. Local derivation of periendothelial cells may be one mechanism that allows for tissue-specific phenotype of the vasculature.[15] Evidence suggests that embryonic endothelial cells may transdifferentiate into vascular smooth muscle cells.[77] Evidence also indicates that some periendothelial cells are derived from the neural crest during embryogenesis and from BM-derived precursors in adults.[78-81] Although some studies have shown pericytes to be potential antivascular targets for tumor therapy,[80,82] other work has suggested that pericytes act to limit tumor metastasis.[83]

Extracellular Matrix

It is thought that whereas interstitial collagens (e.g., collagen I) and provisional plasma-derived fibronectin–fibrin matrices stimulate endothelial tubular morphogenic events, laminin-rich matrices lead to endothelial differentiation and stabilization events.[75] Mice deficient in fibronectin die during embryogenesis and show vascular defects. Type I collagen-deficient mice die of circulatory failure just before birth. Although most tumor vessels are covered by basement membrane, this layer has multiple structural abnormalities consistent with ongoing vascular activation in tumors.[84] ECM proteins or their proteolytic fragments have been shown to inhibit angiogenesis.

Dissolution of the underlying matrix by MMPs and heparanases allows endothelial cells to migrate at the initiation of angiogenesis.[85,86] Matrix-bound growth factors are also released as a consequence of ECM degradation. The balance between positive and negative regulators is the basis of tight control in this process. Tissue plasminogen activator (t-PA) and urokinase plasminogen activator, by generating plasmin, can activate collagenases and other MMPs. Plasminogen activator inhibitors (PAIs) may block angiogenesis at this step. Action of the MMPs is required for angiogenesis, and the tissue inhibitors of MMPs regulate their function.[87]

Cell Adhesion Molecules

Of the various classes of cell adhesion molecules involved in angiogenesis, the integrins have been the most studied.[14,88,89] Although it is universally accepted that integrins and integrin ligands function in angiogenesis, their exact actions remain unclear. In particular, substantial controversy surrounds the role of $\alpha v\beta 3$ integrin.[14,88,90] Immunohistochemical studies localize this integrin to the tips of sprouting vessels. Neutralizing antibodies abrogate angiogenesis and induce vascular cell apoptosis in vivo. However, mice lacking αv show extensive angiogenesis, and mice and humans (Glanzmann thrombasthenia) lacking $\beta 3$ integrin also show normal angiogenesis. Notwithstanding the discrepancies outlined, preclinical studies have validated $\alpha v\beta 3$ and potentially other integrins ($\alpha v\beta 5$, $\alpha 1\beta 1$, $\alpha 2\beta 1$, $\alpha 5\beta 1$, $\alpha 6\beta 4$) as therapeutic antiangiogenic targets, and clinical trials with combination therapy are currently in progress.[91] One of the integrin receptors for fibronectin, $\alpha 5\beta 1$, has been shown to be necessary for vascular development, and $\alpha 2\beta 1$ seems important for the formation of tubes by endothelial cells in vitro. However, there likely is a dynamic regulation of $\beta 1$ integrins during angiogenesis because constitutive activation of this integrin inhibits endothelial sprouting in vitro and angiogenesis in vivo.[92] The junctional proteins VE-cadherin and PECAM-1, and possibly JAM-1, are expressed early in development and have a role in assembling the vasculature.[28,93,94]

Guidance Molecules

Similar to the nervous system, the vascular system forms a highly ordered, branching network. The ordering of this patterned network is dependent on multiple attractive and repulsive cues, many of which are common to both the nervous and vascular systems.[95,96] Whereas VEGF165 acts as an attractive cue to the tip cell of the endothelial sprout, Netrin1 signals to UNC5b on the vasculature act as a repulsive cue. Other guidance pathways implicated in vascular patterning and angiogenesis are ephrinB2–EphB4, plexinD1–semaphorin, and Slit–Robo interactions, as well as the neuropilins. Patterning and specification of small arteries along peripheral nerves in the skin of the embryonic limb involves nerve-derived VEGF; in other situations, neuronal patterning is dependent on the vasculature.[97,98] Thus the congruent patterning of the neural and vascular systems likely is caused by use of common signals and may require cross-talk between the two systems.

Remodeling, Regression, and Apoptosis

Even though the vasculature is laid down before circulation begins, hemodynamic forces are important for maintenance and remodeling. Most of the vessels laid down during vasculogenesis regress or are remodeled. After neovascularization (e.g., during wound healing), the vessels regress when no longer needed. A chronic decrease in blood flow results in narrowing of the vessel lumen. This change in vessel caliber is dependent on an intact and functional endothelium.[99] Remodeling, which involves loss of some vessels as well as changes in lumen diameter and wall thickness, requires both cell death and proliferation (as well as remodeling of the ECM). In addition to survival signals transmitted by integrins, shear stress is important for endothelial survival and vessel healing after injury.[100-102] Oxygen tension is important in vascular maintenance. Hypoxia increases levels of VEGF, which provides signals for vessel maintenance and neovascularization.[103] Hyperoxia, on the other hand, inhibits VEGF expression, which leads to regression and death of retinal vessels.[104] In some models, regression of vessels occurs by apoptosis of vascular cells.[105,106] Endothelial cells express several antiapoptotic molecules to maintain viability when quiescent and when stressed.[107,108] Most likely, an intricate balance between cell death and proliferation is maintained by activators and inhibitors of both processes.

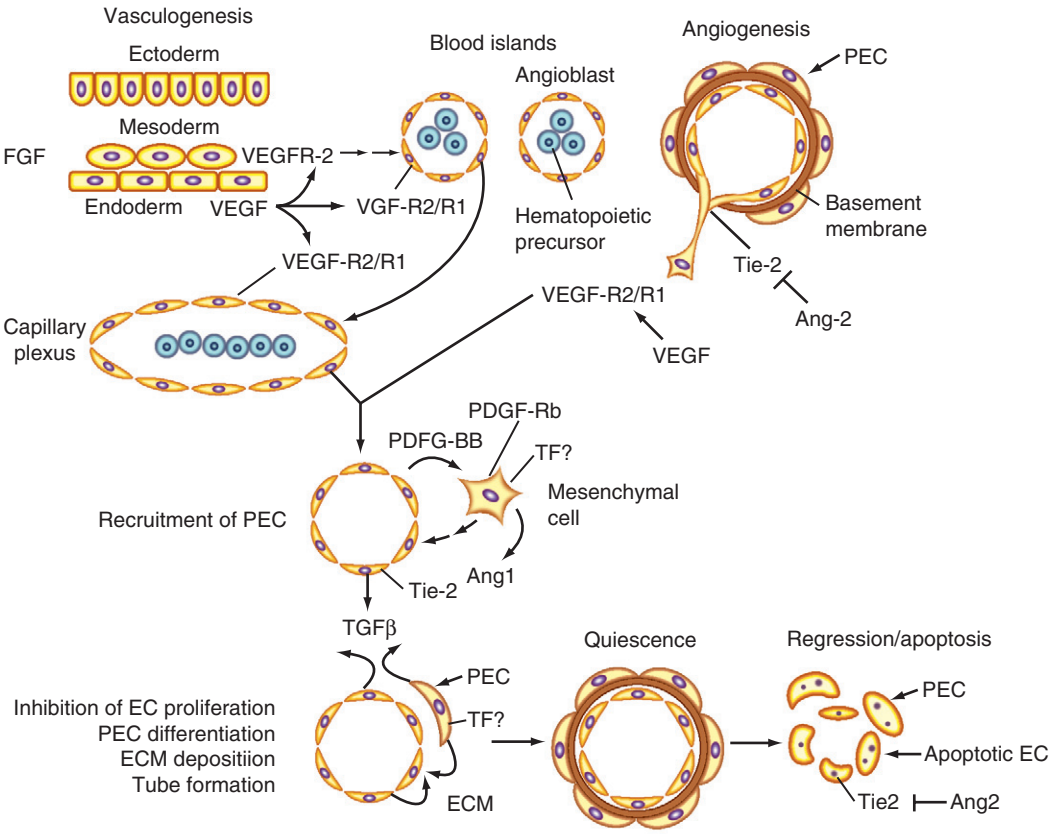

Figure 125-1 MODEL FOR VASCULAR DEVELOPMENT. The role of secreted proteins and membrane receptors in vascular development is highlighted, but other factors such as cell adhesion molecules and extracellular matrix components also contribute significantly. *Ang,* Angiopoietin; *ECM,* extracellular matrix; *FGF,* fibroblast growth factor; *PDGF,* platelet-derived growth factor; *PEC,* periendothelial cell (smooth muscle cell, pericyte); *TF,* tissue factor; *TGFβ,* transforming growth factor-β; *VEGF,* vascular endothelial cell growth factor; *VEGF-R,* vascular endothelial cell growth factor receptor.

Role of Ligand–Receptor Interactions

Numerous factors regulate vascular development and differentiation in a positive or negative fashion. Some of the key molecules and their receptors are discussed here. A model for vascular development is shown in Fig. 125-1.

Inducers of Angiogenesis

Fibroblast Growth Factors

The role of FGFs in vascular development remains murky.[109-111] Because of possible functional redundancy in the numerous family members, assigning specific roles to the various members of the FGF family has been difficult. Evidence suggests that FGF receptors signal an inductive pathway by upregulating VEGFR-2 in differentiating mesoderm before vascular morphogenesis.[111-113] FGF2 may induce neovascularization in adults indirectly through activation of the VEGF–VEGFR pathway.[114]

Vascular Endothelial Growth Factors

Six members of the VEGF family have been identified[70,109,111,115–119]: VEGF-A (also called vascular permeability factor), VEGF-B, VEGF-C, VEGF-D, VEGF-E (a viral ortholog), and placental growth factor. Three members of the receptor tyrosine kinase family[109,118,119]—VEGFR-1 (flt-1), VEGFR-2 (flk-1/KDR), and VEGFR-3 (flt-4)—respond differentially to individual members of the VEGF family. In addition, the coreceptors for VEGF, neuropilin 1 and neuropilin 2, have been identified on arterial and venous endothelial cells, respectively. Neuropilin 1 is a coreceptor for VEGFR-2 that enhances binding of the VEGF-A isoform VEGF165 to VEGFR-2.[118] VEGF-A functions as a homodimer. However, it also heterodimerizes with VEGF-B and placental growth factor, and it has a crucial dose-dependent effect on vasculogenesis.[70,109,111,118,119] Whereas VEGF-A binds VEGFR-1 and VEGFR-2, VEGF-C binds VEGFR-2 and VEGFR-3. Whereas placental growth factor specifically activates VEGFR-1, VEGF-E binds only VEGFR-2.[111,118,119] Lack of VEGFR-2 prevents the development of endothelial cells and a hematopoietic system because cells lacking VEGFR-2 do not reach the correct location to form blood islands.[120] Mice that have been rendered deficient for VEGFR-1 have normal hematopoietic progenitors and abundant endothelial cells, but they do not form capillary tubes or functional vessels.[121] Both VEGFR-2– and VEGFR-1–deficient mice die at an early embryonic stage, as do neuropilin 1– and neuropilin 2–deficient mice. In von Hippel-Lindau disease, development of hemangioblastomas may be caused by stabilization of VEGF mRNA.[122] VEGF is also believed to play a key role in propagating tumor angiogenesis. Whereas tip cell migration has been shown to be dependent on a gradient of VEGF-A, endothelial proliferation in the lengthening vascular stalk is dependent on the absolute concentration of VEGF-A, although both processes require VEGFR-2.[73] Finally, injection of VEGF is capable of relieving limb ischemia by the generation of collateral vessels.[72] Whereas VEGF appears to collaborate with the angiopoietins (Angs) to stimulate vascular development, VE-cadherin acts to temper the VEGF response.[28]

Angiopoietins

The Ang family of secreted glycoproteins comprises four members: Ang1 to Ang4. All four bind to Tie2, a receptor tyrosine kinase.[123-126] Whereas Ang1 and Ang4 act as agonists of Tie2, Ang2 and Ang3 function as antagonists of Tie2.[126] However, the action of Ang2 is context dependent, and in some environments, it may behave as an agonist.[126] Binding of Ang1 to Tie2 results in tyrosine phosphorylation of Tie2 and promotes endothelial cell survival but not proliferation.[123,126] Early in development, Ang1 is found mainly in the myocardium surrounding the endocardium, but it also becomes expressed in the mesenchyme surrounding developing vessels.[123] Disruption of either Ang1 or its receptor Tie2 in the mouse results in embryonic lethality because of similar defects.[124,127] These mice die at a slightly later stage than do VEGFR-deficient mice. Although endothelial cells are present, they have a lack of vascular complexity and a scarcity of periendothelial cells. Reciprocal interactions between the endothelial cells and surrounding matrix and mesenchyme appear to be disrupted. An activating Tie2 mutation in humans causes vascular malformations that show a disproportionate number of endothelial cells compared with smooth muscle cells, resulting in dilated, tortuous vascular channels in certain tissues.[128] Mice engineered to overexpress Ang2 specifically in their vasculature show embryonic lethality and vascular defects that are reminiscent of those seen in Ang1- or Tie2-null embryos.[125] In one proposed model, Ang1–Tie2 coupling mediates vascular maturation by sustaining endothelial cell–periendothelial cell–matrix interactions and may be involved in maintaining endothelial cell quiescence. Because Ang2 is found only at sites of vascular remodeling, Ang2 loosens matrix contacts, thus allowing access and responsiveness to angiogenic factors such as VEGF.[125,126] In the absence of growth factors, disruption of the vessel architecture by Ang2 may result in vascular cell apoptosis and vessel regression. However, Ang2-deficient mice are born alive, and the major defect appears to be lymphatic development.[126] Thus, despite major advances, the data are conflicting. The response of endothelial cells to the Angs likely is context dependent and endothelial cell type specific.[126]

Tie1 is a receptor tyrosine kinase that exhibits structural similarities to Tie2. A ligand for Tie1 has not yet been identified.[109,129] Disruption of the Tie1 gene in mice results in lethality at a much later point in development; Tie1-null mice may survive up to birth.[127,130] $Tie1^{-/-}$ mice die of hemorrhage and edema, implicating Tie1 in signaling the control of fluid exchange across capillaries and in maintenance of vessel integrity under hemodynamic stress. Chimeric mice that express $Tie1^{-/-}$ and $Tie1^{+/-}$ endothelial cells show underrepresentation of $Tie1^{-/-}$ cells in vessels primarily derived by angiogenesis but not in embryonic vessels derived by vasculogenesis, suggesting a differential function for Tie1 in angiogenesis.[131] Evidence also implicates a role for Tie1 in combination with Ang1 in establishing vascular polarity.[132]

Platelet-Derived Growth Factors

The platelet-derived growth factor (PDGF) family is composed of four chains. PDGF-A and PDGF-B can associate in a homodimeric or heterodimeric fashion.[133] Similarly, the receptors α and β are receptor tyrosine kinases that can form homodimers or heterodimers. PDGF-BB can bind the receptors PDGFR-ββ or PDGFR-αβ, but PDGFR-ββ binds only PDGF-BB and not PDGF-AA or PDGF-AB.[109] Mice that are null for PDGF-B die perinatally of renal, hematologic, and cardiovascular abnormalities.[134] The large vessels and heart of these mice are dilated, and microvessels exhibit microaneurysms because of a lack of pericytes.[19,134] PDGFR-β knock-out mice do not show an overtly abnormal cardiovascular phenotype, but generation of chimeric mice demonstrates that $PDGFR\text{-}\beta^{-/-}$ cells are underrepresented in all muscle lineages (smooth, cardiac, and skeletal).[135,136] Thus, it appears that PDGF-BB elaborated by the endothelial cell provides a signal to recruit mesenchymal periendothelial cells as part of the maturation process of vascular morphogenesis. Two novel PDGF chains, PDGF-C and PDGF-D, have been identified.[137] PDGF-CC can bind PDGFR-ββ or PDGFR-αβ, exhibits greater mitogenicity of mesenchymal cells than does PDGF-AA, and promotes wound repair. PDGF-DD activates PDGFR-ββ and possibly PDGFR-αβ. PDGF-DD expression has been found to be elevated in the serum of patients with various types of tumors and has been shown to have transforming and angiogenic activity.[137]

Transforming Growth Factors β

Members of the transforming growth factor-β (TGFβ) family are multifunctional homodimeric peptides with diverse effects on cell proliferation, migration, differentiation, adhesion, and expression of cell adhesion molecules and ECM.[109,138,139] They are secreted as inactive precursors. After being activated, they transmit signals to cells by binding heteromeric complexes of type I and type II serine/threonine kinase receptors. In most cell types, the type I receptor engaged by TGFβ is activin receptor-like kinase 5 (ALK5). However, in endothelial cells, TGFβ can bind and signal through ALK5 and ALK1.[140] Contact between endothelial cells and periendothelial cells is required for production of active TGFβ.[15] Mice lacking TGFβ or TGFβ receptor type II exhibit similar defects in vasculogenesis and hematopoiesis.[138,139] Endothelial proliferation is not affected, but poor contacts between endothelial cell and mesothelial layers in embryos of $TGF\beta^{-/-}$ mice result in a disorganized and reduced vascular network lacking capillary tubes. Mutations in two TGFβ receptors, ALK1 and the accessory TGFβ receptor endoglin, have been linked to the vascular disorder hereditary hemorrhagic telangiectasia.[140] Disruption of TGFβ signaling likely plays a role in the telangiectasia seen in this disorder.

Notch

The Notch family is composed of four receptors (Notch1 through Notch4) and five ligands (Jagged1 and Jagged2 and Delta-like 1 [Dll1], Dll3, and Dll4). Ligand engagement results in a series of proteolytic clips that release the Notch intracellular domain, which then translocates to the nucleus where it effects transcriptional activation via the DNA-binding protein CSL (also called RBP-Jκ or CBF1).[141] Gene targeting studies have revealed a critical role for Notch1, Dll1, Dll4, and Jagged1 in vascular development and remodeling.[141] Dll4–Notch1 signaling between endothelial cells within the angiogenic sprout serves to restrict tip cell formation in response to VEGF.[142-144] Consequently, inhibition of Dll4 in adult mice results in increased endothelial proliferation, sprouting, and branching and increased tumor vascularity.[145,146] However, the vasculature is disorganized and poorly perfused; thus Dll4 blockade inhibits tumor growth in several models.[145,146]

Coagulation Factors

Tissue factor (TF) is a member of the cytokine receptor superfamily. In addition to its role in initiating coagulation as a cofactor for factor VII, TF may be involved in intracellular signaling. TF knock-out mice have abnormalities of their large vessels and microvasculature secondary to defects in mesenchymal cell and periendothelial cell accumulation and function.[20] Elevated TF expression in various tumors and the associated angiogenic endothelium has been reported.[147] Expression of mutant oncogenes (K-*ras,* EGFR) or tumor suppressor genes (PTEN, p53) leads to increased TF expression and activity, and this may link tumor angiogenesis and the hypercoagulable states manifested in cancer.[147] Abnormal development of the vasculature also affects 50% of mice that are deficient in factor V. The affected mice die in utero, and the 50% embryonic lethality is similar to that observed in thrombin receptor–deficient mice that die without obvious coagulation defects.[148] Factor V–dependent generation of thrombin may be important for early vascular development by signaling through the thrombin receptor.[149] Thrombin can promote angiogenesis through a mechanism that is independent of fibrin formation.[149,150] Studies have suggested that thrombin can stimulate release of angiogenic factors (e.g., VEGF-A) from tumor cells and platelets as well as induce VEGFR-2 on endothelial cells.[150]

Clinical trials have revealed that treatment with low-molecular-weight heparins improves the survival time of cancer patients receiving chemotherapy, an effect that appears to be independent of the anticoagulant properties of the low-molecular-weight heparins.[151,152] Although antiangiogenic effects of specific heparanase-generated fragments of unfractionated heparins have been demonstrated in vitro, the mechanism of the antitumor effect remains to be defined.

The potential involvement of fibrinolytic factors in angiogenesis has been mentioned. Interestingly, fragments 1 and 2 of prothrombin have been reported to inhibit angiogenesis, and various other fragments of coagulation and fibrinolytic proteins also may inhibit angiogenesis.[153]

Other Factors

Various other families of ligand–receptor pairs play a role in angiogenesis. They include ephrin-Eph, Wnt-frizzled, and sonic hedgehog-smoothened. Various chemokines have been shown to modulate angiogenesis in either a positive or negative fashion.

Inhibitors of Angiogenesis

As with the angiogenesis inducers, multiple factors have been reported to negatively regulate vascular morphogenesis.[72,153] Of interest is a class of endogenous angiogenesis inhibitors that are fragments of larger proteins that have little or no angiogenesis-related activity in their intact form. They include fragments of ECM proteins such as fibronectin, collagen type IV α3 chain (tumstatin), and collagen type XIII (endostatin), as well as coagulation protein fragments such as plasminogen (angiostatin) and antithrombin.[153] The mechanism of action of these protein fragments depends on the particular polypeptide, but the functional effect usually is inhibition of endothelial proliferation or induction of apoptosis.[153-155] Other endogenous inhibitors include interferons, chemokines, and interleukin-12 (IL-12).

More than 100 compounds are in clinical trials attempting to cause regression of tumors by inhibiting angiogenesis.[156] These compounds can be broadly divided into those that act directly by targeting the angiogenic endothelial cell and those that act indirectly by targeting activators of angiogenesis. The latter category includes targeting of oncogenes (e.g., mutant EGFR or Her2) because many aberrantly activated oncogenes have been shown to induce expression of angiogenic factors. The first clear-cut evidence of efficacy in clinical trials of an angiogenic inhibitor for tumor therapy came from regimens directed against the VEGF pathway (e.g., bevacizumab).[157,158] Because of the short improvement in overall and progression-free survival with the addition of VEGF inhibitors over standard chemotherapy, it is likely that heterogeneity and inherent instability of tumor cell populations result in the selection of malignant cells that feed their vasculature through factors other than VEGF. In this regard, use of indirect angiogenic inhibitors still suffers from the likelihood of tumors becoming resistant to the therapy.

Whether the mechanism of action of these inhibitors is truly caused by the abrogation of a functional vascular supply is an open question. VEGF inhibitors "normalize" the aberrant, leaky tumor vasculature. Other than in renal cancer, VEGF inhibitors have shown effect only when used in combination chemotherapy regimens, which has led to the proposal that VEGF pathway inhibition improves vessel functionality and perfusion, thus facilitating delivery of chemotherapeutic agents.[157,158] VEGF–VEGFR signaling also acts in autocrine fashion within some tumor cell populations, raising the possibility that positive outcomes may have as much to do with direct tumor kill as with an antiangiogenic effect. Finally, as with organogenesis, the vasculature may provide a juxtacrine or paracrine role in supporting tumor viability and proliferation independent of the provision of a circulatory system for delivery of nutrients and oxygen.[47]

Some of the more common side effects observed with use of VEGF-A inhibitors were not predicted a priori but may be understandable in retrospect. For instance, hypertension and arterial thrombosis are common side effects. Two possible reasons may explain the hypertensive side effect. One is that VEGF directly activates endothelial nitric oxide synthase (eNOS) and thus may be responsible in part for basal production of NO.[159] Another potential explanation is that podocyte-derived VEGF is required for proper glomerular function throughout life.[47] Heterozygous loss of podocyte VEGF results in hypertension and proteinuria in adult mice.[47] Given that proteinuria is also commonly seen in patients treated with VEGF inhibitors, the latter explanation would tie two of the side effects seen. The reasons for arterial thrombosis are less obvious. Because arterial circulation is more dependent on VEGF, it is possible that arterial endothelial apoptosis serves as a nidus for localized activation of coagulation and platelet aggregation. Apoptotic endothelial cells have been shown to increase thrombin-generating capacity and bind to unactivated platelets and leukocytes.[160-162]

More recently the use of PDGF inhibitors to target pericytes has been shown to be a potentially effective antiangiogenic strategy, particularly in combination with antiendothelial (anti-VEGF) molecules.[80,82] "Metronomic" or low-dose, frequent scheduling of traditional cytotoxic agents also is reported to have an antiangiogenic effect and has proven efficacious in animal studies.[163] Antivasculogenic therapy directed against recruitment of BM-derived vascular precursors may have a role in future cancer therapeutic regimens, but thus far the evidence is weak at best.[66]

Arteriogenesis

Arteriogenesis is a term coined to distinguish the development of collateral vessels in adults from the process of angiogenesis.[164,165] Remodeling of a preexisting collateral arteriole is thought to be caused by flow-induced changes secondary to occlusion of a supply artery. The consequent increase in shear stress through the collateral arteriole activates endothelial cells, resulting in monocyte recruitment and infiltration into the media. Elaboration of various cytokines, growth factors, and proteases from monocytes and endothelial cells causes matrix degradation, smooth muscle cell proliferation, and rapid enlargement of the preexisting arteriole. Factors thought to promote arteriogenesis include FGF-2, placental growth factor, PDGF-BB, TGFβ1, monocyte chemoattractant protein 1, and GM-CSF.[165,166]

Lymphangiogenesis

The lymphatics comprise a low-flow, low-pressure system that collects extravasated fluid from the tissues and transfer it back to the venous system via the thoracic duct. Lymphatic vessels also serve an immune function by transporting lymphoid and antigen-presenting cells to lymphoid organs.[167] Lymphatic vessels share features with blood vessels, but they also exhibit differences. Lymphatic vessels develop shortly after blood vessels and may arise de novo from precursor mesenchymal cells (lymphangioblasts) in a process akin to vasculogenesis.[168] Alternatively, other studies suggest that specific venous endothelial cells differentiate to lymphatic endothelium in response to signals that have yet to be determined.[169] VEGF-C and VEGF-D, by activating VEGFR-3 and Ang2 potentially through Tie2 activation, are growth factors necessary for lymphatic vessels.[170] The α9β1 integrin also is necessary for proper lymphatic development, and the homeobox transcription factor Prox1 appears to induce transdifferentiation of venous to lymphatic endothelial cells.[169-171] Lymphedema can be caused by congenital defects, parasitic (filariasis) or neoplastic obstruction, or surgical resection. Congenital lymphedema (Milroy disease) is linked to inactivating mutations of VEGFR-3.[167] Whether lymphatic vessel density in human tumors correlates with disease progression is not clear, but in animal models, induction of lymphangiogenesis by VEGF-C or VEGF-D promotes lymph node metastasis.[167]

Relationship Between Vascular Development and Hematopoiesis

Hematopoietic cells and endothelial cells are intertwined in several ways. First, there is the likely existence of a common precursor (see Vasculogenesis above). Second, the endothelium is intimately involved in hematopoiesis, having a supportive role structurally and nutritionally. Finally, the endothelium organizes the controlled egress and ingress of hematopoietic cells in hematopoietic and other tissues. The last issue is covered in Interaction of Blood Cells With the Vessel Wall section.

Bone marrow stromal cells secrete cytokines, produce ECM, and are in direct cellular contact with hematopoietic cells, thereby providing a microenvironment suitable for hematopoietic proliferation, differentiation, and self-renewal.[172] Many studies demonstrate the supportive role of endothelium in hematopoiesis.[173-175] The physical proximity of endothelium and hematopoietic precursors within the BM and the requirement of blood cells to transit BM endothelium to reach the circulation is presumptive evidence of an important role for endothelium. BM endothelial cells constitutively express high levels of IL-6, stem cell factor, granulocyte colony-stimulating factor, and GM-CSF.[173] Both yolk sac and BM endothelial cells support long-term proliferation and differentiation of hematopoietic cells in vitro.[173] However, endothelial cells also have been reported to inhibit hematopoiesis.[176]

Significant evidence now indicates that hematopoietic stem and progenitor cells are not randomly distributed in the BM but rather are spatially and possibly physically associated with the endosteum and the blood vessels.[175] Functional differences between the osteoblastic and vascular niches have been described. It has been suggested that whereas the osteoblastic niche maintains quiescence of hematopoietic stem cells, stem and progenitor cells that are activated for differentiation and mobilization reside at the vascular niche.[174] Translocation of megakaryocyte progenitors to the vicinity of the BM sinuses is sufficient to induce megakaryocyte maturation and platelet production.[175] However, a study has identified CXCL12 (SDF-1)-abundant reticular cells that are located in close proximity to the sinusoidal endothelium as well as the endosteum.[177] The authors confirmed that the CXCL12–CXCR4 signaling axis is required for maintenance of hematopoietic stem cells in the BM, and these findings raise the possibility that the vascular and osteoblastic niches may not be that different.[177] In all likelihood, endothelial cells and osteoblasts, in concert with other stromal cells, provide a finely tuned system to modulate hematopoiesis in the BM such that differentiation, proliferation, and self-renewal occur in a regulated fashion.

Human endothelial cells have been reported to express receptors for IL-3, stem cell factor, erythropoietin, and thrombopoietin and show functional responses to IL-3 and erythropoietin.[178-180] The shared responses to growth factors, combined with the importance of macrophages in angiogenesis and the production of cytokines by monocytes and macrophages, suggest that hematopoietic cells play a reciprocal role in maintaining the endothelium.

PHYSIOLOGIC FUNCTIONS OF THE ENDOTHELIUM

The Endothelium as a Barrier

The microvessels (capillaries and postcapillary venules) act as the exchange vessels of the circulation. However, as with other endothelial functions, vessel permeability is dependent on the type of vessel and its location. Movement of lipophilic and low-molecular-weight hydrophilic substances between blood and tissue is virtually unimpeded, but the vessels are selectively permeable to macromolecules. This semiselective barrier is necessary to maintain the fluid balance between intravascular and extravascular compartments, yet antibodies, hormones, cytokines, and other molecules must have access to the interstitial space for the initiation and potentiation of various processes, including inflammation, immune response, and wound repair.

Movement of macromolecules across the vessel wall is governed by (1) hydrostatic and oncotic pressure gradients; (2) physicochemical properties of the molecule, such as size, shape, and charge; and (3) properties of the barrier. The barrier of the vessel wall is formed by the cellular components, endothelial cells, and pericytes, as well as by the charge and compactness of the matrix components, glycocalyx, and basement membrane. Macromolecules can pass either directly through the endothelial cell (transcellular path) or between adjacent endothelial cells (paracellular path). Surprisingly, the mechanisms of macromolecular movement remain controversial, and data generated by physiologists, morphologists, and cell biologists have not been consolidated in a model that satisfies the findings of the different groups.[181]

To explain cellular transport in endothelium, physiologists have proposed the existence of two sets of "pores" based on experiments measuring the movement of dextran and other macromolecules—a small pore of radius 3 to 5 nm for transport of water and small hydrophilic molecules and a large pore of radius 25 to 60 nm for macromolecular transport.[181-183] Although water mainly moves across the continuous endothelium via the paracellular route, a significant proportion (≤40%) can traverse the endothelium via the transcellular route by water-transporting membrane channels, the aquaporins.[184] Macromolecular transport into cells can proceed by receptor-mediated systems, such as clathrin-coated pits, in which the molecules usually are targeted to the lysosome, but may be transported through the cell. Alternatively, molecules can be moved across the cell by plasmalemmal vesicles or caveolae, which are abundant in capillary endothelial cells. Caveolae are 50- to 100-nm membrane invaginations that can participate in transcytosis as well as in the translocation of glycosylphosphatidylinositol-linked proteins into the cytoplasm and in transmembrane signaling.[185] Because of the known leakiness of tumor microvasculature, investigators have studied these microvessels and identified a structure designated the vesiculovacuolar organelle.[186] These organelles are grapelike clusters of interconnecting uncoated vesicles and vacuoles that span the entire thickness of vascular endothelium, thereby providing a potential transendothelial connection between the vascular lumen and the extravascular space.[186] Interestingly, their function is enhanced by injection into normal skin of VEGF, which is known to increase the permeability of vessels.[186] Localization of caveolin to vesiculovacuolar organelles suggests that this structure is a fusion of caveolae.[186]

During inflammation, binding of neutrophils to the endothelium results in the generation of oxidants that can mediate endothelial cell injury and increase permeability.[187] Upon adhesion of neutrophils to the endothelium, leukocyte CD18 (β2 integrin)-mediated signals trigger the release of the neutrophil cationic protein called heparin-binding protein/CAP37/azurocidin, which in turn induces formation of gaps between endothelial cells and macromolecular efflux.[188] Thrombin, an inflammatory mediator, can increase endothelial permeability by several mechanisms resulting from activation of its receptor on endothelial cells.[189-191] First is an increase in transcellular vesicular permeability. Second is increased paracellular permeability that results from phosphorylation of endothelial cell nonmyosin light chains and contractile activity generated by movement of actin and myosin filaments past each other. The contraction and retraction of endothelial cells are accompanied by "loosening" of intercellular junctions and focal integrin contacts with the ECM. Finally, thrombin may alter the repulsive effect of the negatively charged glycocalyx. An increase in paracellular permeability may result from alteration of cell–cell contacts present at tight junctions and adherens junctions secondary to posttranslational modification of components of these junctions such as claudins and VE-cadherin.[181] Pericyte contractility also has been hypothesized as a mechanism for increasing permeability in inflammatory states.[191]

The Endothelium as a Nonthrombogenic Surface

The molecular mechanisms of hemostasis and thrombosis are addressed in Chapters 115 and 116 and 118 through 120. This

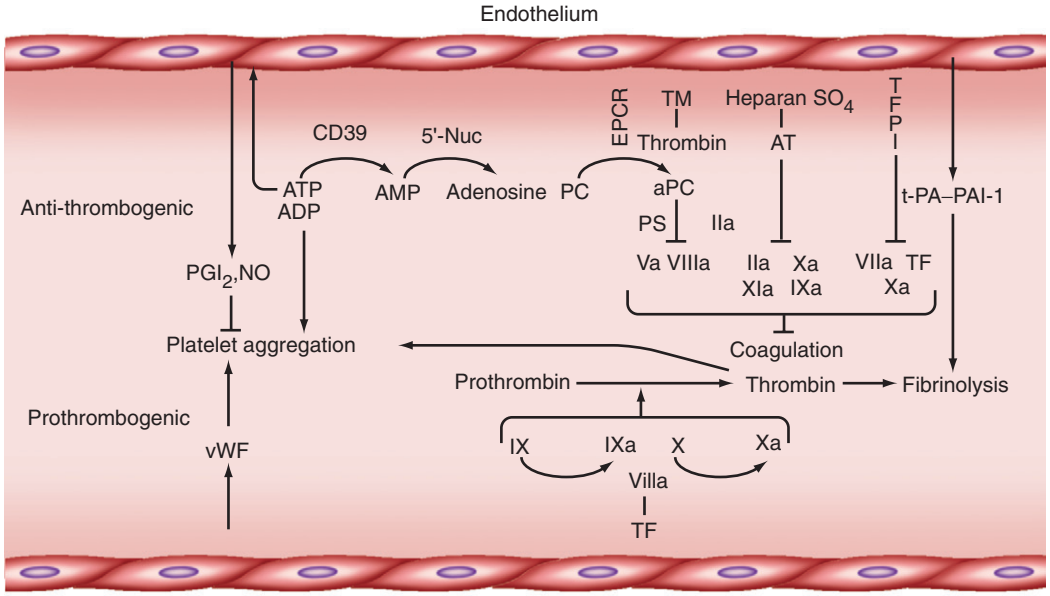

Figure 125-2 OVERVIEW OF ENDOTHELIAL FUNCTION IN COAGULATION. *ADP,* Adenosine diphosphate; *AMP,* adenosine monophosphate; *AT,* antithrombin; *ATP,* adenosine triphosphate; *EPCR,* endothelial protein C receptor; *5′-Nuc,* ecto-5′-nucleotidase; *NO,* nitric oxide; *PAI-1,* plasminogen activator inhibitor 1; *PC,* protein C; *PGI_2,* prostaglandin I_2 (prostacyclin); *PS,* protein S; *TF,* tissue factor; *TFPI,* tissue factor pathway inhibitor; *TM,* thrombomodulin; *t-PA,* tissue plasminogen activator; *vWF,* von Willebrand factor.

section places the endothelium in the appropriate context in these processes. An overview of endothelial cell contributions to the anticoagulant and procoagulant states is shown in Fig. 125-2. Normal unperturbed endothelium presents a nonthrombogenic surface to the circulation by inhibiting platelet aggregation, preventing the activation and propagation of coagulation and enhancing fibrinolysis.[192-196] These activities are accomplished by both passive and active processes. Conversely, when injured or under inflammatory conditions, the endothelium may become procoagulant.

When in close proximity to endothelial cells, platelets become unresponsive to agonists. This inhibition of platelet aggregation is accomplished by secretion of prostacyclin (prostaglandin I2 [PGI_2]) and NO and by surface expression of an ecto-adenosine phosphatase (ADPase)/CD39/nucleoside triphosphate diphosphohydrolase (NTPDase-1).[195,197] Prostacyclin is synthesized mainly by vascular endothelial and smooth muscle cells as a product of arachidonic acid metabolism. It inhibits platelet activation, secretion, and aggregation, as well as monocyte interactions with endothelial cells. It also causes vascular smooth muscle cell relaxation. NO similarly has a wide range of functions, including inhibition of platelet adhesion, activation, and aggregation. Most of the NO released from endothelial cells is elaborated abluminally, where it acts on the smooth muscle cell to cause vasodilation. However, some NO may enter the lumen and thereby diffuse into platelets. Prostacyclin and NO can act synergistically to reverse platelet aggregation.[195] The released platelet agonist, adenosine diphosphate (ADP), can be inactivated by endothelial membrane-associated CD39.[197] Metabolism of adenosine triphosphate (ATP) and ADP to adenosine monophosphate (AMP) by CD39 eliminates platelet recruitment and returns platelets to their resting state. Adenosine, which is generated by hydrolysis of AMP by ecto-5′-nucleotidase, acts to inhibit platelet aggregation and cause vasodilation. ATP/ADP can stimulate purinoreceptors on endothelial cells, resulting in synthesis and release of PGI_2 and NO.[198]

Endothelial cells use three main pathways to inhibit thrombin generation and limit coagulation[192,194,199,200]:

1. Antithrombin system: Heparan sulfate proteoglycans are secreted onto the luminal surface of endothelial cells and into the subendothelium. Heparan sulfates are capable of binding and activating antithrombin III, thereby accelerating inactivation of several procoagulant serine proteases, including thrombin, factor Xa, and factor IXa.
2. Protein C[201]: Thrombomodulin on the surface of endothelial cells binds thrombin. This coupling inhibits the coagulant properties of thrombin and increases its affinity for protein C, which it cleaves and activates. Activation of protein C by the thrombin–thrombomodulin complex is augmented by its binding to the endothelial cell protein C receptor. Protein S, which is thought to be synthesized primarily by the endothelial cell, acts as a cofactor for protein C but itself also has anticoagulant properties. Independent of the presence of activated protein C, free protein S is able to inhibit the prothrombinase and intrinsic tenase complexes and interact directly with factors Va and VIIIa.
3. Tissue factor pathway inhibitor (TFPI)[202]: TFPI is a Kunitz-type serine protease inhibitor that modulates TF-initiated coagulation. TFPI binds to and directly inhibits the TF–factor VIIa–factor Xa complex. It is mainly produced by and bound to endothelial cells, likely to surface glycosaminoglycans. There is also a plasma pool bound to low-density lipoprotein (LDL).

If coagulation occurs despite the many anticoagulant mechanisms, endothelial cells also provide proteins to promote fibrinolysis.[194] Endothelium is a major source of t-PA.[203,204] Approximately 40% of t-PA is bound to its inhibitor, PAI-1, which is also secreted by endothelial cells. Stresses such as exercise, acidosis, hypoxia, shear forces, increased venous pressure, and thrombin cause release of t-PA[203,204] and presumably activate plasminogen. Receptors for plasminogen and t-PA are present on the endothelial cell surface, allowing for effective localized production of fibrinolytic activity.

Although intact endothelium is necessary to maintain blood in a fluid state and inhibit coagulation under normal conditions, injured endothelium can rapidly downregulate its anticoagulant functions and become procoagulant even without overt vascular damage as occurs with trauma or surgery. Further tissue injury or vascular pathology also leads to exposure of the underlying matrix, which is procoagulant by virtue of its binding to and activation of platelets. Endothelial cells that have been induced to undergo apoptosis in vitro become procoagulant. Apoptotic endothelial cells expose

phosphatidylserine on their surface and downregulate their anticoagulant properties. Apoptotic endothelial cells and vascular smooth muscle cells also increase thrombin formation in recalcified citrated plasma, and apoptotic endothelial cells show increased adhesion to unactivated platelets.[160,161,205] Thrombosis resulting from procoagulant changes induced by endothelial apoptosis could contribute to the pathogenesis of diverse diseases.[206]

Even without endothelial death, perturbation of the vascular lining by inflammatory mediators could tip the balance such that the endothelium converts from a nonthrombogenic to a procoagulant surface because of downregulation of anticoagulant properties as well as induction of procoagulant properties. For example, the setting of acute inflammation is associated with increased release of vWF, platelet-activating factor, and fibronectin, all of which may potentiate thrombus formation. Tumor necrosis factor (TNF), IL-1, and lipopolysaccharide can increase the expression of PAI-1 in endothelial cells with downregulation or no change in t-PA levels, thereby impairing fibrinolysis. TNF, IL-1, and lipopolysaccharide also have been shown to downregulate thrombomodulin as well as to induce expression of TF on cultured endothelial cells. However, whether endothelial cells express TF on their luminal surfaces in vivo is controversial.[207] More recently, circulating microparticles generated by leukocytes and vascular cells have been shown to be a source of bloodborne TF and to contribute to coagulation.[208] Although most microparticles probably are derived from platelets and monocytes, endothelial-derived microparticles may be an important source of circulating TF under conditions of drastic activation.[208,209]

Control of Vascular Tone

Control of vascular tone is orchestrated primarily by a balance between endothelium-derived vasodilators (NO, PGI_2, and endothelium-derived hyperpolarizing factor [EDHF]) and vasoconstrictors (endothelin-1 [ET-1] and superoxide). In addition to inhibiting platelet aggregation, NO and PGI_2 act as vasodilators.[210,211] NO is produced by conversion of L-arginine to L-citrulline by NO synthase (NOS). Three forms of NOS exist: a constitutive NOS in neuronal tissue; an inducible enzyme found in macrophages and other cells that plays a role in NO-induced cytotoxicity; and a constitutively active endothelial form, NOSIII (eNOS).[212] The inducible form of NOS also is present in endothelial cells and may be responsible for the uncontrolled vasodilation seen in septic shock.[212] Injection into the forearm of L-arginine analogues that inhibit NOS causes substantial vasoconstriction. Conversely, eNOS-deficient mice are hypertensive, suggesting that NO release is crucial for maintaining basal vasodilation.[210,211] The major physiologic stimulus for continuous production of NO in vivo is shear stress. The action of NO on platelets (antiaggregatory), endothelial cells, and smooth muscle cells (relaxation) is caused by activation of guanyl cyclase and formation of cyclic guanosine 3′,5′-cyclic monophosphate. Whereas NO is quite unstable, the formation of *S*-nitrosothiols in the presence of oxygen and thiols provides a stable reservoir of NO.[213] Hemoglobin is an avid scavenger of NO, which may account for the vasoconstriction observed with administration of cell-free, hemoglobin-based RBC substitute.[214] Physiologically, however, *S*-nitrosohemoglobin acts as a regulator of blood flow. Deoxygenation is accompanied by an allosteric change in *S*-nitrosohemoglobin that releases the NO group, relaxing blood vessels to bring blood flow in line with local oxygen requirements.[215]

Prostacyclin (PGI_2), on the other hand, does not appear to have as global a role in vasodilation as does NO. PGI_2 is synthesized mainly by endothelial cells and acts locally at sites of injury. It may counterbalance the vasoconstriction induced by the platelet-produced arachidonic acid metabolite thromboxane A_2 (TXA_2). Most PGI_2 is released luminally, where it has an antiplatelet effect. Whereas prostacyclin transduces a cellular signal by increasing the levels of cyclic AMP (cAMP), TXA_2 signals via the phosphoinositol pathway and lowering of cAMP levels. Synthesis of prostaglandins begins by the action of cyclooxygenases (COX-1 and COX-2) on arachidonic acid. Aspirin inhibits COX irreversibly in both platelets and endothelial cells. However, the clinical effect is seen primarily in platelets for two reasons.[211,212] One reason is that platelets, being nonnucleated, cannot synthesize new COX, but endothelial cells can. Therefore, TXA_2 synthesis recovers only when new platelets enter the circulation, but COX production by endothelial cells restores PGI_2 levels within a few hours. The second reason is that platelets encounter orally administered aspirin before it is deacetylated by the liver and diluted by the venous circulation.

Early experimental evidence suggested that endothelial cells release other relaxing factors (i.e., EDHF), which act by increasing the membrane potential of smooth muscle cells. Hyperpolarization of isolated coronary arteries occurs in the presence of an arginine analogue, a NOS inhibitor, and indomethacin, a COX inhibitor, suggesting that EDHF, NO, and prostanoids contribute differentially to relaxation in human coronary arteries.[216] The nature of EDHF is unclear, but it encompasses different biologic mechanisms. These mechanisms involve an increase in intracellular calcium concentration, the opening of calcium-activated potassium channels, and the hyperpolarization of endothelial cells, resulting in an endothelium-dependent hyperpolarization of smooth muscle cells.[217] Smooth muscle cell hyperpolarization may occur through direct myoendothelial electrical coupling or through accumulation of potassium ions in the intercellular space. Findings suggest that EDHF represents cytochrome P450-linked arachidonate metabolites in some blood vessels but also lipoxygenase derivatives and hydrogen peroxide.[217]

Endothelin-1 is a 21-amino-acid peptide, released preferentially at the abluminal surface of endothelial cells, that exhibits potent vasoconstrictor activity.[218,219] Of the three known ETs, only ET-1 is produced by endothelial cells. At least two receptors (ET-A and ET-B) bind to all three ETs. Whereas ET-A is abundantly expressed on smooth muscle cells, ET-B is predominantly expressed on endothelial cells. The vasoconstrictor activity of ET-1 is preferentially mediated by ET-A receptors on smooth muscle cells. Engagement of ET-B on endothelial cells by ET-3 may paradoxically cause a transient vasodilation. Little evidence indicates that ET-1 plays a role in essential hypertension, but it might contribute to pregnancy-induced hypertension and may play a role in reperfusion injury after ischemia.[219] ET-1 does appear to play a role in pulmonary arterial hypertension, and the dual ET receptor antagonist bosentan has been approved for treatment of this disease.[220]

Another seemingly important regulator of vascular tone is the superoxide anion.[210,221] The source of this free radical may be the endothelium itself or inflammatory cells that have been recruited to sites of injury or inflammation. Interaction of superoxide radicals and NO produces peroxynitrite and reduces the concentration of NO. Peroxynitrite can oxidize LDL and deleteriously modify other proteins, thereby causing endothelial dysfunction. Increased production of superoxide inhibits synthesis of PGI_2 but not that of TXA_2.[221]

The endothelium expresses angiotensin-converting enzyme at its surface; this enzyme converts angiotensin I to angiotensin II, a potent vasoconstrictor. The interaction among ET, angiotensin II, and α-adrenergic agonists in the pathogenesis of hypertension is complex.[222] An altered balance of the vasoactive substances described in this section has been proposed to cause endothelial dysfunction and the attendant vascular pathology observed in atherosclerosis, hypertension, and diabetes mellitus. Alteration of vascular function in these diseases then may perpetuate endothelial dysfunction and, consequently, worsen disease.

Interaction of Blood Cells With the Vessel Wall

Leukocytes

In the absence of any inflammatory stimulus, neutrophils circulate freely and do not interact significantly with the endothelium. This contrasts with continuous, low-level physiologic traffic of monocytes and lymphocytes across the vessel wall. Monocytes emigrate from the bloodstream to develop into tissue macrophages that may exhibit

tissue- or organ-specific functions. To maintain immune surveillance of tissue, lymphocytes recirculate between blood and lymphatics, gaining entrance to the latter at the high endothelial venule of postcapillary venules in lymphoid tissue.

Intravital microscopic studies have established a sequence of events involved in leukocyte emigration at extravascular sites of inflammation. Under conditions of flow, leukocytes first tether to and then roll along the endothelium of postcapillary venules adjacent to the site of inflammation. Some of the rolling leukocytes are activated and adhere firmly. The adherent leukocytes migrate along the endothelial surface and diapedese between endothelial junctions to enter the extravascular tissue. These steps in emigration tethering, rolling, activation, firm adhesion, and diapedesis also are involved in lymphocyte emigration at high endothelial venules. They result from the interaction of distinct leukocyte and endothelial receptors in an adhesion cascade (Fig. 125-3; see Chapter 16).[223,224] Rolling is observed only under flow conditions and is the consequence of shear forces acting on the leukocyte and adhesive interactions between selectin receptors and their glycoconjugate counterstructures.[225] It is initiated primarily by activation of the endothelium by extravascular stimuli such as bacterial-derived products or by endogenous mediators produced by the endothelium or cells in tissue. Early on, rolling is mediated by endothelial P-selectin, which is rapidly translocated from Weibel-Palade bodies to the luminal surface, and L-selectin on leukocyte microvilli. E-selectin is involved only at later time points because it is not constitutively expressed by endothelium but rather is induced over hours by de novo synthesis.

For leukocytes to circulate freely, their integrin receptors must be minimally adhesive, but they also must be able to increase binding rapidly at sites of inflammation. After being tethered to endothelium by selectin interactions, leukocyte integrin receptors are activated by endothelial membrane-expressed platelet-activating factor, endothelial membrane-bound chemokines, or locally secreted chemoattractants. Activation of leukocyte integrins involves changes in receptor affinity or affinity-independent receptor clustering,[226] which promotes firm adhesion to endothelial ligands, which are members of the immunoglobulin gene superfamily (IgSF). These IgSF ligands are constitutively expressed (ICAM-1, ICAM-2), further upregulated (ICAM-1), or induced (VCAM-1) by inflammatory mediators (Table 125-1). Although these activation-dependent increases in leukocyte

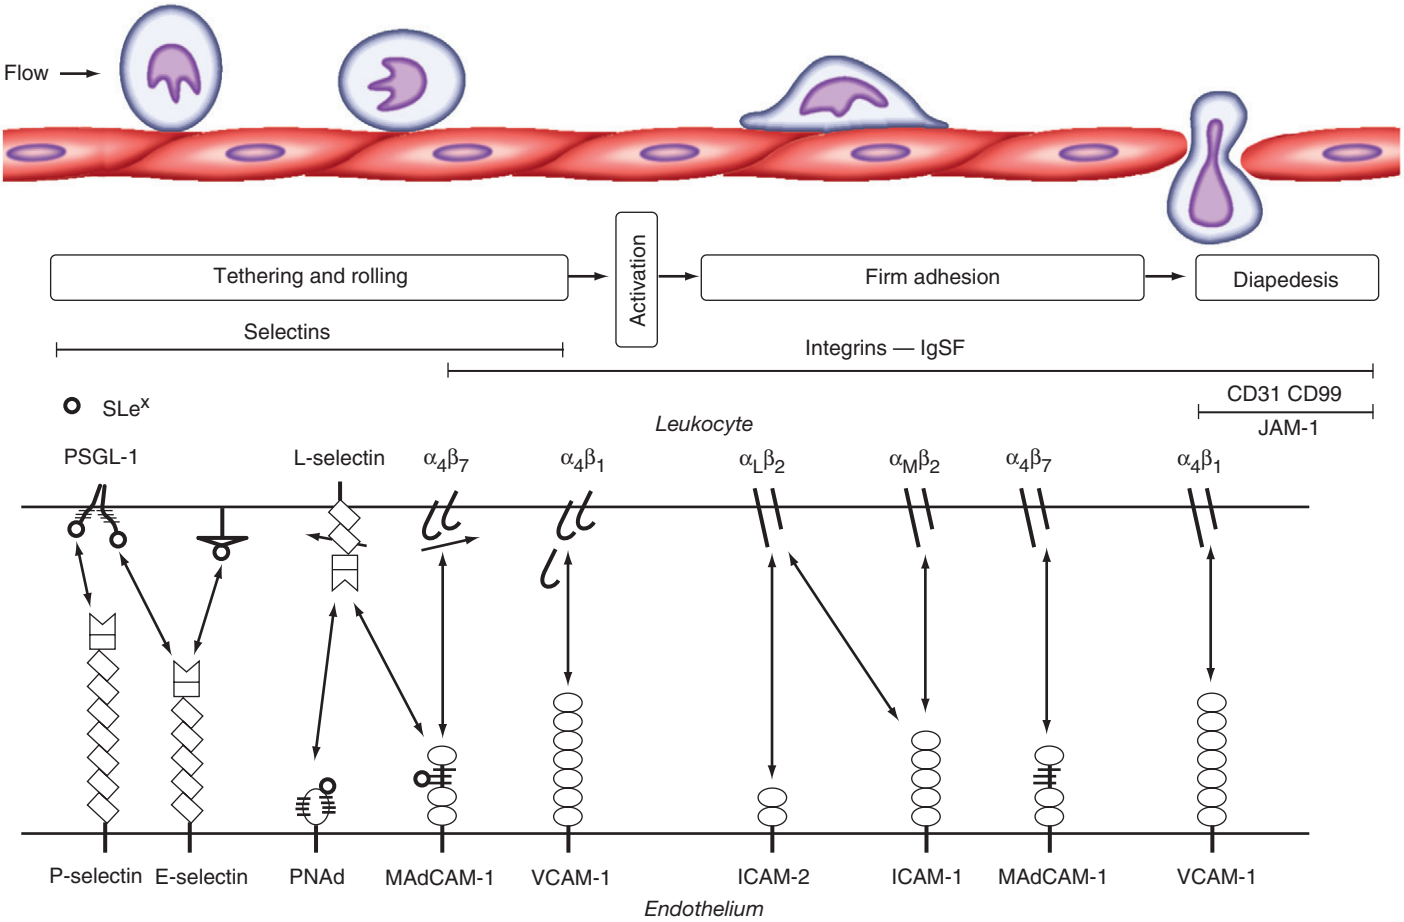

Figure 125-3 ADHESION CASCADE. Under conditions of flow, leukocytes first tether to endothelial ligands and then roll along the vessel wall. Tethering is mediated predominantly by interaction of P-selectin and L-selectin with their cognate glycoconjugate ligands. P-selectin binds to sialyl Lewis X (SLe^x) and sulfate residues expressed on P-selectin glycoprotein ligand 1 (PSGL-1). L-selectin binds to an uncharacterized ligand(s) on inflamed endothelium and to sulfated SLe^x-like moieties on peripheral node addressin (PNAd) and mucosal addressin cell adhesion molecule 1 (MAdCAM-1) on high endothelial venules. E-selectin, $\alpha_4\beta_1$ (very late antigen 4 [VLA-4]), and $\alpha_4\beta_7$ stabilize rolling initiated by P-selectin and L-selectin. E-selectin recognizes SLe^x on PSGL-1 and other glycoproteins or glycolipids. After tethering and rolling, leukocyte integrin receptors are activated, most often by chemoattractants (e.g., chemokines) via G protein–coupled receptors. After activation, integrin receptors engage endothelial immunoglobulin gene superfamily ligands to promote firm adhesion. Leukocyte $\alpha_L\beta_2$ (leukocyte function antigen 1 [LFA-1]) binds to intercellular adhesion molecules 1 and 2 (ICAM-1 and ICAM-2), $\alpha_M\beta_2$ (macrophage 1 [Mac-1]) to ICAM-1, $\alpha_4\beta_1$ (VLA-4) to vascular cell adhesion molecule 1 (VCAM-1), and $\alpha_4\beta_7$ to MAdCAM-1. The adherent leukocyte then migrates across endothelium to interendothelial junctions, where it diapedeses between endothelial cells via leukocyte integrin receptors and their endothelial immunoglobulin gene superfamily ligands as well as endothelial junctional proteins such as CD31, CD99, and junctional adhesion molecule 1 (JAM-1).

Table 125-1 Endothelial Cell Activation*

Agonist	Response
Thrombin	Secretion of vWF, P-selectin, TFPI, and PDGF Synthesis of PAF, IL-8, IL-6, and E-selectin
IL-1β, TNF-α, LPS	Synthesis of adhesion molecules (ICAM-1, VCAM-1, E-selectin), chemokines (IL-8, MCP-1), cytokines (IL-6, CD40), procoagulant proteins (TF, PAI-1, t-PA, u-PA), and cytoprotective molecules (A1, IAP) Downregulation of anticoagulant proteins (TM)
Reduced/disturbed shear stress	Increased expression of proinflammatory genes (e.g., VCAM-1, ICAM-1, MCP-1)
VEGF	Decreased eNOS activity Increased expression of cytoprotective genes (A1, MnSOD), Ang2, COX-2

Ang, Angiopoietin; *A1,* Bcl-2 homologue; *COX-2,* cyclooxygenase 2; *eNOS,* endothelial nitric oxide synthase; *IAP,* inhibitor of apoptosis protein; *ICAM,* intercellular adhesion molecule; *IL,* interleukin; *LPS,* lipopolysaccharide; *MCP,* monocyte chemoattractant protein; *MnSOD,* manganese superoxide dismutase; *PAF,* platelet-activating factor; *PAI,* plasminogen activator inhibitor; *PDGF,* platelet-derived growth factor; *TF,* tissue factor; *TFPI,* tissue factor pathway inhibitor; *TM,* thrombomodulin; *TNF,* tumor necrosis factor; *t-PA,* tissue plasminogen activator; *u-PA,* urokinase-type plasminogen activator; *VCAM,* vascular cell adhesion molecule; *VEGF,* vascular endothelial growth factor; *vWF,* von Willebrand factor.
*Selected agonists and responses. Many other stimuli (e.g., lipoproteins, hypoxia, microbes, and microbial products) have been reported to upregulate or downregulate various endothelial responses.

integrin binding to endothelial IgSF ligands are necessary for shear-resistant firm adhesion, subsequent leukocyte migration over the endothelium requires reversible adhesion caused by cyclic modulation of receptor avidity.[227]

There are several caveats regarding the current multistep model of initial selectin-mediated rolling and subsequent integrin-mediated firm adhesion.[228] First, selectin-mediated rolling is not a prerequisite for emigration under conditions of reduced flow, as might occur at sites of inflammation.[229] Second, the model was developed from observations in the systemic microcirculation, where leukocyte emigration occurs in postcapillary venules under relatively low shear forces. However, selectins do not appear to play a major role in neutrophil emigration in the pulmonary microcirculation, where emigration occurs predominantly in capillaries,[230] or in the liver microvasculature, where leukocytes emigrate primarily in sinusoids.[231] Third, under some conditions leukocytes are able to tether and roll via receptors other than selectins and α4 integrins (e.g., CD44[232] or VAP-1[233]). Finally, several other adhesion pathways have been implicated in leukocyte adhesion to endothelium in vitro, and their roles in the adhesion cascade in vivo remain to be defined.[228]

When adherent, leukocytes migrate upon the endothelial luminal surface. Upon encountering an intercellular junction, some leukocytes diapedese between endothelial cells, enter extravascular tissue, and then migrate to the site of inflammatory or immune reaction.[234,235] This process of transendothelial migration uses leukocyte integrin interactions with endothelial IgSF ligands[236] and several junctional proteins, including PECAM-1 (CD31),[237] JAM-1,[238] and CD99.[239] Diapedesis involves signaling by the leukocyte to the endothelial cell that triggers opening of endothelial cell junctions.[240] Although leukocyte migration is primarily paracellular (i.e., through endothelial cell–cell junctions), under certain circumstances, leukocytes may emigrate by a transcellular pathway.[241]

Leukocyte recruitment is terminated by several mechanisms. Whereas E-selectin and P-selectin are removed from the endothelial cell surface by endocytosis,[242] L-selectin is cleaved from leukocytes by a membrane protease.[243] Decay of cytokine, chemokine, or chemoattractant generation leads to gradual resolution of endothelial adhesion molecule expression and integrin activation. Locally expressed mediators, such as NO,[244] TGFβ,[245] and Fas ligand,[246] also inhibit further leukocyte adhesion to endothelium.

The adhesion molecules involved in leukocyte trafficking from bloodstream to tissue have emerged as important therapeutic targets. Extensive preclinical studies showed that blockade of leukocyte or endothelial adhesion molecules was efficacious in diverse disease models,[247] prompting the development of adhesion antagonists for clinical trials in a variety of diseases. However, results were disappointing overall, with many unsuccessful clinical trials of various adhesion antagonists in multiple disease indications.[248,249] Moreover, the report of progressive multifocal leukoencephalopathy, a rare viral infection of the central nervous system, in several patients treated with the α4-integrin antagonist natalizumab[250] highlights the risks of targeting molecules that are pivotal in host defense and repair as well as in disease. Nevertheless, the potential of antiadhesion therapy is demonstrated by the approval of two integrin antagonists: efalizumab for treatment of psoriasis[251] and natalizumab for treatment of multiple sclerosis.[252]

Platelets

Similar to neutrophils, unactivated platelets do not interact with unperturbed endothelium. After a vascular injury that produces endothelial denudation or retraction, platelets rapidly adhere to the exposed subendothelium. As discussed in greater detail in Chapters 115 and 116, at high shear rates, this initial adhesion does not require platelet activation and involves platelet glycoprotein Ib/V/IX (GPIb-V-IX) binding to vWF in the subendothelial matrix and platelet GPVI binding to collagen in the injured arterial wall. Platelet activation occurs after adhesion, leading to platelet spreading mediated by integrin receptors binding to matrix components and aggregation mediated by fibrinogen binding to GPIIb/IIIa (αIIbβ3).

Evidence indicates that platelets can bind directly to activated endothelium in vivo via endothelial P-selectin[253] and PECAM-1[254] and to roll on venular endothelium via interaction of platelet GPIbα and endothelial P-selectin.[255] Platelets have been shown to bind to high endothelial venules in vivo via platelet P-selectin.[256] In vitro platelets can adhere to intact endothelium via a platelet GPIIb/IIIa-dependent bridging mechanism involving platelet-bound adhesive proteins and the endothelial cell receptors ICAM-1, αVβ3 integrin, and GPIbα.[257] Platelet adhesion to intact endothelium via these various pathways may contribute to thrombus formation in the circulation and may provide a link between thrombosis and inflammation in diseases such as atherosclerosis.[258] Platelet–endothelial interactions also may contribute to the pathogenesis of thrombotic thrombocytopenic purpura. Normally, ultralarge vWF remains attached to endothelium via P-selectin until it is cleaved by the plasma metalloproteinase ADAMTS-13 (a disintegrin and metalloproteinase with thrombospondin). Failure of this mechanism in thrombotic thrombocytopenic purpura because of a deficiency of ADAMTS-13 may lead to spontaneous platelet adhesion to endothelium and microvascular thrombosis.[259]

Red Blood Cells

Plasmodium falciparum-infected and sickled RBCs interact significantly with endothelium, and these adhesive interactions are thought to play an important role in the pathogenesis of human diseases.

Among the human malarial parasites, only *P. falciparum* modifies the surface of the parasitized RBs so that asexual parasites and gametocytes are able to adhere to the vascular endothelium.[260,261] Binding of trophozoite- and schizont-infected RBCs to endothelium not only allows the parasite to escape destruction in the spleen but also may contribute to the pathogenesis of cerebral malaria.[261,262] Multiple endothelial adhesion receptors have been implicated in mediating cytoadherence of infected RBCs, including P-selectin, ICAM-1, VCAM-1, and CD36.[263]

Binding of young sickled RBCs to postcapillary endothelium with secondary trapping of poorly deformable, often irreversibly sickled cells is thought to be an important pathogenic factor in vasoocclusive events.[264] Several interactions between sickle RBC receptors and endothelial ligands have been described, including α4β1/VCAM-1[265]; α4β1/Lutheran blood group (basal cell adhesion molecule)[266]; and ICAM-4/αVβ3.[267] The adhesive proteins thrombospondin and vWF promote adhesion by serving as bridging factors between various sickle RBC and endothelial adhesion molecules. In addition to direct adhesion to endothelium, sickle RBC binding to adherent leukocytes has been proposed as a mechanism for sickle cell vascular occlusion.[268] As with leukocyte adhesion to endothelium in inflammatory and immune disease, drugs targeting sickle RBC adhesive interactions with endothelial cells or leukocytes may prove useful in preventing or treating vasoocclusive crises.

Endothelial Cell Activation and Dysfunction

Although once viewed as a passive barrier between blood and tissue, the endothelium now is evident to be a dynamic and heterogeneous organ that responds to diverse stimuli, ranging from coagulation proteins and cytokines to hemodynamic forces and growth factors. Activation of endothelial cells induces a complex proinflammatory and prothrombotic phenotype as well as expression of certain cytoprotective genes (see Table 125-1).[269,270] Multiple transcription factors, particularly nuclear factor-κB[271] and early growth response 1,[272] regulate these responses.[269] Endothelial activation undoubtedly is an important event in host defense and repair, but it also may contribute to the pathogenesis of diverse diseases, ranging from sepsis[273] to atherosclerosis.[274]

Endothelial dysfunction is characterized by a reduction in the bioavailability of vasodilators, particularly NO, leading to impairment of endothelium-dependent vasodilation, or by an increase in endothelium-derived contracting factors.[275] Endothelial dysfunction is prominent in atherosclerosis but also has been described in diabetes, preeclampsia, hypertension, uremia, and other diseases. In a broader sense, endothelial dysfunction encompasses proinflammatory and procoagulant changes as well as apoptotic cell death.[206,276,277]

A number of noninvasive approaches for assessing endothelial function in vascular diseases have been developed. Endothelial vasodilatory responses can be evaluated by high-resolution ultrasound measurement of flow-mediated vasodilation or by plethysmography of changes in forearm blood flow during reactive hyperemia.[278] Endothelial activation can be assessed in plasma by circulating markers such as soluble endothelial adhesion molecules (e.g., sVCAM-1, sICAM-1, sE-selectin) and endothelial coagulation proteins (e.g., vWF and thrombomodulin)[279] or endothelial microparticles.[280] Circulating endothelial cells reflect significant vascular damage or cell death.[281]

CHAPTER 126

MEGAKARYOCYTE AND PLATELET STRUCTURE

Joseph E. Italiano, Jr., and John H. Hartwig

Platelets are small anucleate fragments that are formed from the cytoplasm of megakaryocytes and have a characteristic discoid shape. To assemble and release platelets, megakaryocytes become polyploid by endomitosis and follow a maturation program that results in the conversion of the bulk of their cytoplasm into multiple long processes called *proplatelets*. To produce its quota of 1000 to 2000 platelets, a megakaryocyte may protrude as many as 10 to 20 proplatelets, each of which begins as a blunt protrusion that over time thins and branches repeatedly. Platelets form selectively at the ends of proplatelets. As platelets develop, their content of granules and organelles is delivered to them in a stream of individual particles moving from the megakaryocyte cell body to the nascent platelet buds at the proplatelet tips. Platelet formation can be arbitrarily divided into two phases. The first phase takes days to complete and requires megakaryocyte-specific growth factors. Massive nuclear proliferation to 16 to 32 × N and enlargement of the megakaryocyte cytoplasm occur as the platelet is filled with cytoskeletal proteins, platelet-specific granules, and sufficient membrane to complete the platelet assembly process. The second phase is relatively rapid and can be completed in hours. During this phase, megakaryocytes generate platelets by remodeling their cytoplasm first into proplatelets, then preplatelets, which undergo fission to generate discoid platelets.

MEGAKARYOCYTE DEVELOPMENT

Endomitosis

Hematopoietic stem cells, which are endowed with the genetic capacity to differentiate into multiple lineages, are induced down the pathway to become megakaryocytes by their exposure to certain growth factors.[1] Megakaryocytes become polyploid (i.e., 4N, 16N, 32N, 64N) through repeated cycles of DNA replication without cell division.[2-5] Normally ploidy ranges from 4 to 64 times the haploid DNA complement, but the majority of cells fall within three ploidy classes (8N, 16N, and 32N), with 16N being dominant (Fig. 126-1).[6,7] Ploidy number appears to be a predetermined event, possibly signifying genetic diversity among megakaryocyte populations. Megakaryocyte polyploidization results in a functional gene amplification whose likely function is an increase in protein synthesis.[8] This process, called *endomitosis,* is a shortened mitosis caused by a block in late anaphase.[9,10]

Whereas cells undergoing diploid mitoses proceed through cytokinesis and complete abscission division, megakaryocytes exhibit regression of the cleavage furrow and reenter G_1 as polyploid cells.[1] During polyploidization of megakaryocytes, the nuclear envelope breaks down, and an abnormal spherical mitotic spindle forms. The spindle has attached chromosomes that align from a position equidistant from the spindle poles. Sister chromatids segregate and move toward their respective poles (anaphase A). However, the spindle poles fail to move apart and do not undergo the microtubule-driven separation typically observed during anaphase B. Individual chromatids are not moved to the poles, and subsequently a single nuclear envelope encapsulates the entire set of sister chromatids.[9,10] In most cell types, checkpoints and feedback controls ensure that DNA replication and cell division are tightly coupled. Megakaryocytes appear to be an exception to this rule, indicating they have managed to deregulate this process. Proposed mechanisms for regulating endomitosis include a reduction in mitosis-promoting factor[11,12] or decreased expression of cyclin B.[12-15] Cyclins appear to play a critical role in directing endomitosis. Cyclin D3 is overexpressed in the G_1 phase of maturing megakaryocytes,[16] but a triple knockout of cyclins D1, D2, and D3 in mice does not appear to affect megakaryocyte development.[17] In contrast, cyclin E-deficient mice exhibit a profound defect in megakaryocyte development.[18] The molecular programming involved in endomitosis is characterized by the mislocalization or absence of at least two critical regulators of mitosis: the chromosomal passenger proteins Aurora-B/AIM-1 and survivin. AIM-1, a serine/threonine kinase in the Aurora family that is implicated in mitosis, is downregulated as megakaryocyte polyploidization occurs, suggesting its loss may lead to the abortive mitosis and polyploidization.[19,20] One explanation for endomitosis could be inhibition of microtubule-based forces in anaphase B. Spindle pole separation during anaphase B is believed to be powered by the sliding of antiparallel interdigitating microtubules past each other[21] by the mitotic kinesin-like protein 1 that localizes at regions of overlapping microtubules during anaphase B and has been shown to slide microtubules past one another in vitro.[22] Therefore lack of spindle pole separation during endomitosis may result from failure of megakaryocytes to undergo normal spindle orientation and/or the absence of signals that localize or activate a kinesin motor molecule that provides force for sliding.

Cytoplasmic Maturation

Megakaryocytes, the largest of the hematopoietic cells, undergo a pronounced cytoplasmic maturation to attain their large volumes (15,000 fL). Cytoplasmic maturation begins during endomitosis and increases considerably after all DNA amplification has ended (Fig. 126-2). Megakaryocytes enlarge dramatically as they mature, reaching sizes of 100 to 150 μm in diameter in culture and in bone marrow. During this process, the megakaryocytic cytoplasm rapidly fills with platelet-specific proteins, organelles, and membrane systems that ultimately are subdivided and packaged into platelets (Fig. 126-3). Their cytoplasmic space expands and, except for the most cortical regions, becomes densely filled with internal membranes that subsequently serve as the repository for the plasma membrane to be regurgitated for coating proplatelets as they extend.[23] This internal membrane system is one of the most striking features of a mature megakaryocyte and has been referred to as the demarcation membrane system (DMS). The DMS, first described by Yamada[24] in 1957, consists of an extensive, tortuous, branching network of membrane channels composed of flattened cisternae and tubules. Initially, the DMS was proposed to play an essential role in platelet formation by defining preformed "platelet territories" or "platelet fields" within the megakaryocyte cytoplasm.[25,26] Release of individual platelets was postulated to occur by massive fragmentation of the megakaryocyte cytoplasm along DMS fracture lines between these fields. However, studies demonstrating that platelets are

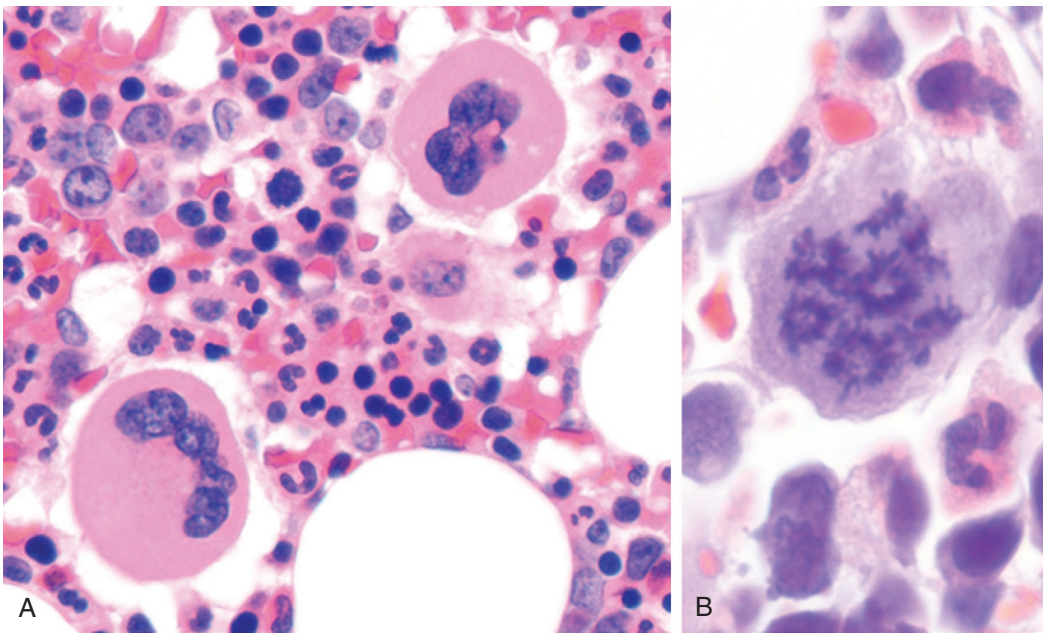

Figure 126-1 POLYPLOID MEGAKARYOCYTES IN THE BONE MARROW. Large polyploid megakaryocytes are seen in the bone marrow on a typical hematoxylin- and eosin-stained slide and are recognized by their abundant pink cytoplasm and large nuclei **(A)**. The degree of polyploidization is difficult to determine. Rarely, megakaryocytes can be seen in mitosis **(B),** and when chromosomes are aligned in metaphase plates, the high ploidy level become quite apparent. In the mitotic figure illustrated, the megakaryocyte is a 16N form with eight 2N metaphase plates.

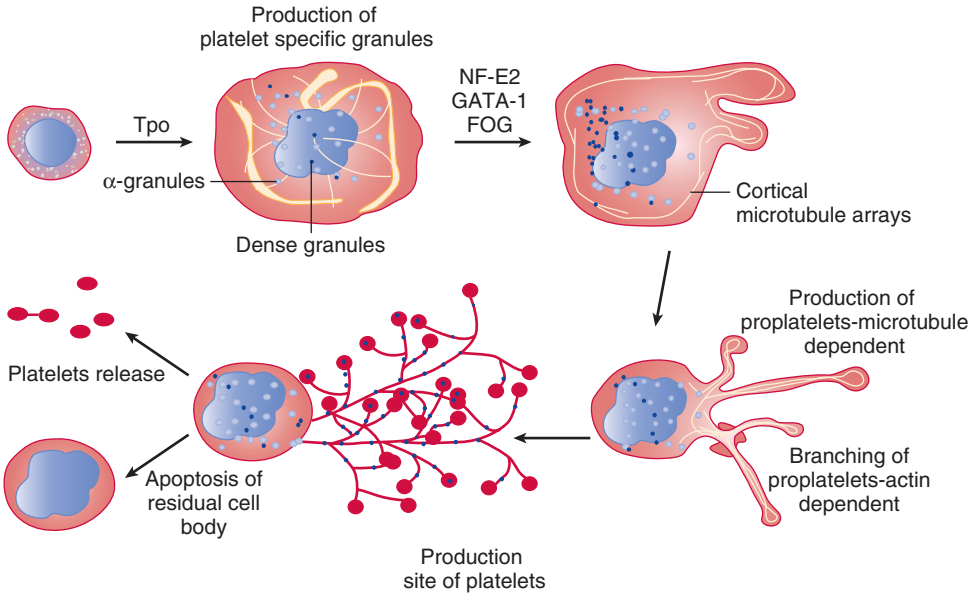

Figure 126-2 SUMMARY OF THE MAJOR EVENTS THAT LEAD TO PLATELET FORMATION AND RELEASE FROM MEGAKARYOCYTES. Hematopoietic stem cells are converted into megakaryocytes by exposure to the specific growth factor thrombopoietin (TPO). TPO initiates a maturation program that amplifies the megakaryocyte DNA and leads to synthesis of platelet-specific proteins. In particular, cytoskeletal elements, membrane systems, and receptor proteins are made in bulk, and the megakaryocyte becomes filled with platelet-specific granules. Platelet production begins when microtubules aggregate in the cell cortex, and one pole of the megakaryocyte spontaneously elaborates pseudopodia. These begin as large blunt pseudopodia, which subsequently thin and branch into proplatelets. The branching reaction is dependent on a localized assembly of actin and is inhibited by drugs that disrupt actin filaments. Platelets are assembled primarily at the ends of the proplatelets. Intracellular organelles are delivered to the platelet buds along microtubule tracks in the shafts. Platelets are released from the ends of proplatelets.

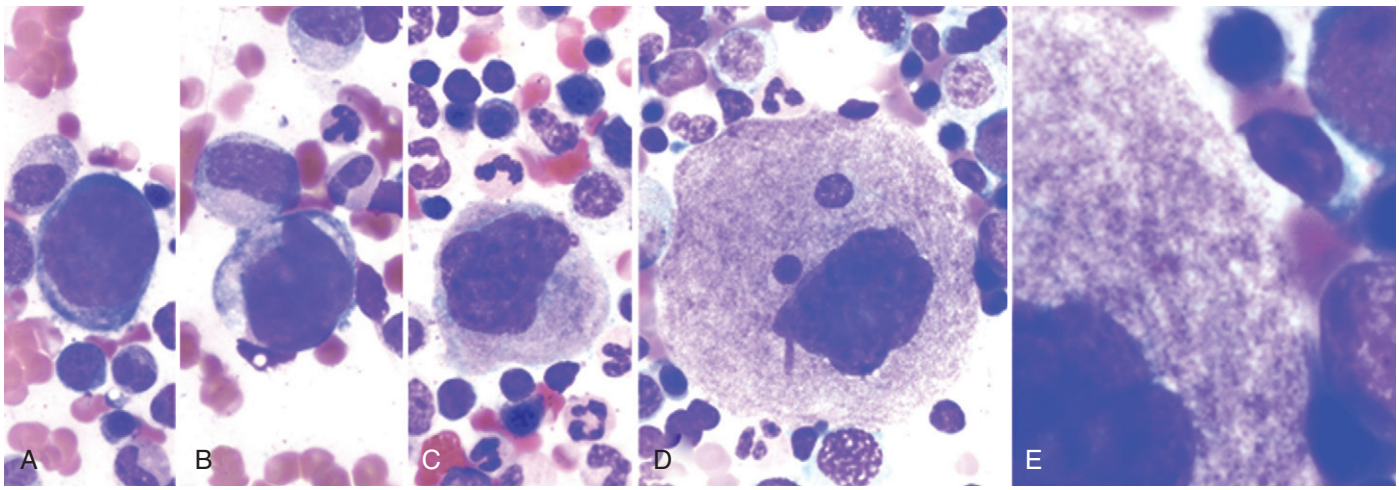

Figure 126-3 PLATELET PRODUCTION IN THE MEGAKARYOCYTE. **A,** Immature polyploid megakaryoblast with little differentiation. **B,** Megakaryocyte with early Golgi zone. **C,** Early platelet production in cytoplasm. **D,** Late-stage megakaryocyte with abundant internal membranes, organelles, and platelet-specific proteins. **E,** Early formation of demarcation membranes.

primarily assembled and released from proplatelet ends (see Platelet Formation, later in this chapter) are inconsistent with this notion and indicate instead that the DMS functions predominantly as a membrane reserve for proplatelet formation.[23] Direct visualization of mature DMS containing phosphatidylinositol 4,5-bisphosphate suggests that it is the source of proplatelet membranes.[2] Maturing megakaryocytes, like other granulated cells, contain an abundance of ribosomes and rough endoplasmic reticulum, where protein synthesis occurs. During this phase of megakaryocyte development, the cytoplasm fills with cytoskeletal proteins, platelet-specific receptors and secretory granules, and normal cellular organelles such as mitochondria and lysosomes.

One of the hallmark features of the mature megakaryocyte is its abundance of platelet-specific secretory granules. The two specific granules destined for platelets are α-granules and dense granules. α-Granules, the more abundant and larger of the two (200 to 500 nm in diameter), contain proteins that enhance platelet adhesion, promote cell-cell interactions, regulate angiogenesis, and stimulate vascular repair. α-Granules store matrix proteins and contain glycoprotein receptors in their membranes (Fig. 126-4, *A*). The bulk of cellular P-selectin and a portion of $\alpha_{IIb}\beta_3$ and the glycoprotein Ib/IX/V complex (GPIb-IX-V, a receptor for von Willebrand factor [vWF]) are expressed in the membranes of α-granules. Adhesion molecules within the granules include vWF, fibrinogen, fibronectin, vitronectin, and thrombospondin. α-Granule proteins can derive from different sources. Some proteins, such as α-thromboglobulin and vWF, are synthesized by megakaryocytes. However, fibrinogen, also a major component of α-granules, is not synthesized by megakaryocytes and is taken up from plasma by an endocytic mechanism requiring fibrinogen binding by $\alpha_{IIb}\beta_3$. Although little is known about the intracellular trafficking of proteins in megakaryocytes, experiments using cryosectioning and immunoelectron microscopy suggest that multivesicular bodies are an essential intermediate stage in the formation of platelet α-granules. During megakaryocyte development, large (≈0.5 μm) multivesicular bodies undergo a gradual transition from granules containing 30- to 70-nm internal vesicles to granules containing secretion concentrates.

The second and smaller type of platelet granule is the dense granule. Platelets contain relatively few dense granules, which are approximately 150 nm in diameter. Dense granules have electron opaque cores and function primarily to recruit additional platelets to sites of vascular injury. Dense granules contain the soluble activating agents serotonin and ADP as well as divalent cations. When the megakaryocyte reaches a certain point of maturation, proplatelet production begins, and granules are sent into the proplatelets destined for platelets.

REGULATION OF MEGAKARYOCYTE DEVELOPMENT

The development of megakaryocytes and the process of platelet biogenesis occur within a complex bone marrow environment where both cytokines and adhesive interactions play an essential role. Megakaryocytes are imprisoned within the subendothelial layer of the bone marrow sinuses where development and platelet biogenesis are regulated at multiple levels by several cytokines. Thrombopoietin (Tpo), which is synthesized in bone marrow and liver, is the principal regulator of thrombopoiesis. Tpo also plays a central role in hematopoietic stem cell survival and proliferation. Circulating levels of Tpo induce proliferation and maturation of megakaryocyte progenitors by binding to the c-Mpl receptor and signaling induction. Tpo regulates all stages of megakaryocyte development, from the hematopoietic stem cell stage through cytoplasmic maturation. Tpo increases platelet production by increasing both the number and size of individual megakaryocytes. c-Mpl activation is regulated by a complex array of signaling molecules that turn on specific transcription factors (see Transcriptional Regulation of Platelet Formation, later in this chapter) to drive megakaryocyte proliferation and maturation. Although Tpo appears to function as the main regulator of megakaryocyte development, it is not exclusive in this action. The cytokine stem cell factor, granulocyte-macrophage colony-stimulating factor, FLT ligand, interleukin (IL)-3, IL-6, IL-11, and erythropoietin also can regulate megakaryocyte development but appear to function mainly in concert with Tpo. Mice that lack Tpo or its receptor c-Mpl have approximately 15% of the normal platelet count. The discovery of Tpo in 1994 and the development of primary megakaryocyte or mouse embryonic stem cell cultures that can be induced to faithfully reconstitute platelet formation have provided systems for studying megakaryocytes in the act of making platelets in vitro. Megakaryocytes isolated from mouse fetal liver and incubated with Tpo for 4 to 5 days mature into huge polyploid cells that are capable of generating and releasing large numbers of platelets. In a similar fashion, mouse embryonic stem cells can be induced to mature into large polyploid megakaryocytes in the presence of stromal cells and Tpo, IL-6, and IL-11. This process requires 10 to 12 days, during which the conversion of embryonic stem cells into hematopoietic stem cells very likely occurs in the first half of the time period and the maturation of hematopoietic stem cells into proplatelet-producing megakaryocytes in the second half. Human embryonic stem cells can be coaxed to differentiate into mature megakaryocytes,[3] although the process takes several more days in culture. Recently, platelets have been generated from human induced pluripotent stem cells in culture using a doxycycline-controlled c-MYC expression vector.[4]

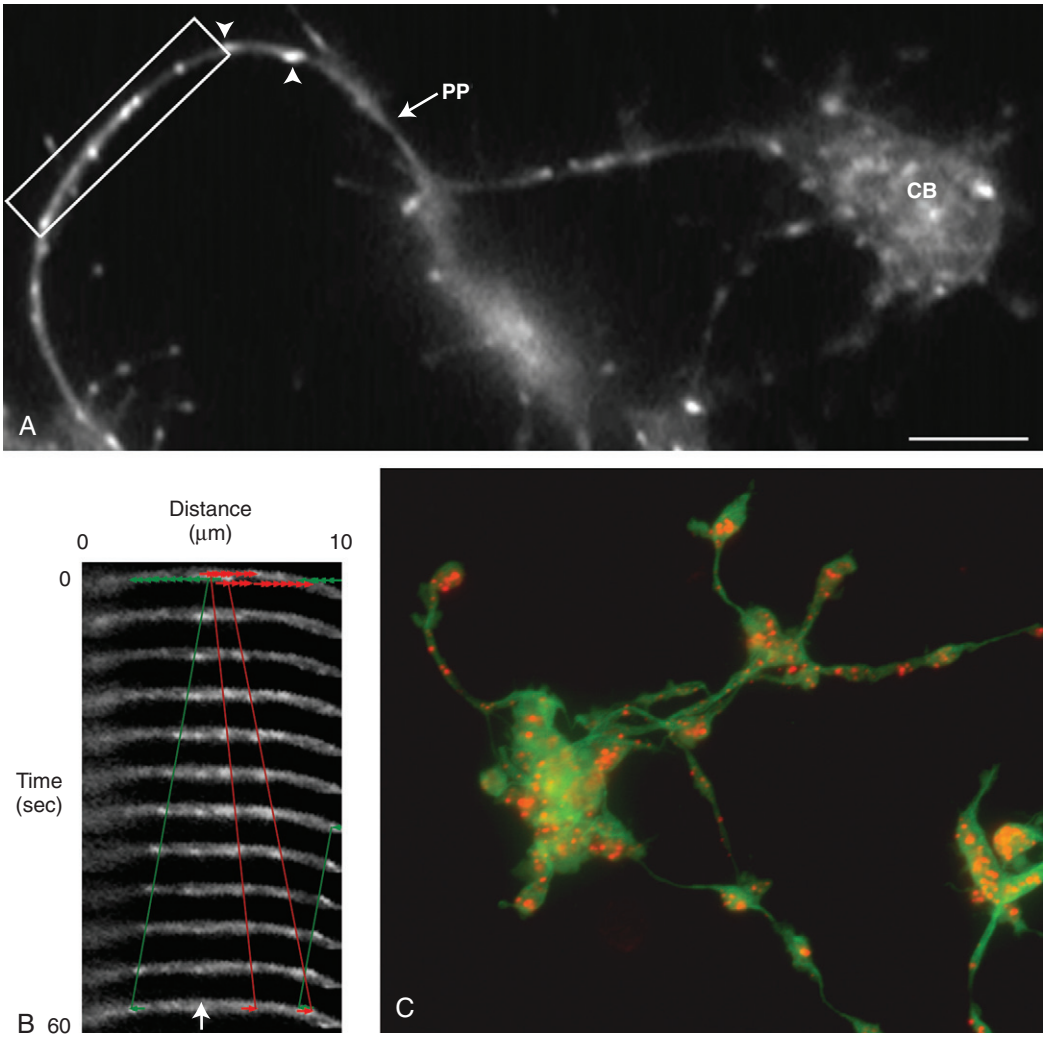

Figure 126-4 MICROTUBULE DYNAMICS DURING PROPLATELET FORMATION. **A,** Visualization of plus-end microtubule assembly in living megakaryocytes expressing end-binding protein 3 (EB3)–green fluorescent protein (GFP). First frame from the time-lapse sequence (shown in **B**) of a living megakaryocyte that was retrovirally directed to express EB3-GFP. The cell body (CB) is at the right of the micrograph, and proplatelets (PP) extend to the left. EB3-GFP labels growing microtubule plus ends in a characteristic "comet" staining pattern that has a bright front and a dim tail. **B,** The kymograph shows movement over time. Images are every 5 seconds. EB3-GFP comets undergo bidirectional movements in proplatelets, demonstrating that microtubules are organized as bipolar arrays. Some EB3-GFP comets move toward the tip and are highlighted in green; others that move toward the cell body are highlighted in *red.* **C,** Distribution of α-granules in megakaryocytes and proplatelet projections visualized by fluorescence microscopy. α-Granules are stained with Alexa 568 *(red)*–labeled anti–von Willebrand factor antibodies. The proplatelets have been co-stained with Alexa 488 *(green)* antitubulin antibodies to highlight the microtubules.

PLATELET FORMATION

Proplatelets and the Cytoskeletal Mechanics of Platelet Formation

The discovery of Tpo and the development of megakaryocyte cultures that reconstitute platelet formation in vitro have allowed visualization of megakaryocytes in the act of forming platelets.[5] The actual mechanical process of platelet production begins when mature megakaryocytes start to elaborate proplatelets (see Fig. 126-2 and Fig. 126-5). This process is distinguished by the erosion of one pole of the megakaryocyte cytoplasm (see Fig. 126-5). Multiple thick pseudopodia are extended and subsequently elongate to yield thin tubules. As these slender tubules grow, they branch repeatedly and develop periodic densities along their length that impart a beaded appearance.[5,6] The first insight into the cytoskeletal mechanics of platelet formation dates from the work of Tablin and colleagues, who showed that proplatelet formation is dependent on microtubules; that is, proplatelet elaboration is inhibited by microtubule poisons. Microtubule poisons are effective because the extension of proplatelets from the megakaryocyte is mediated by the assembly of microtubules and their reorganization into cortical bundles. Cortical bundles align in the shafts of proplatelets, and proplatelet elongation is driven by sliding movements between overlapping microtubules composed of these bundles.[7] The microtubule bundles form loops at the end of each proplatelet, and ultimately a single microtubule is rolled into a coil at the proplatelet end to define the platelet territory. Cytoplasmic tubulin in solution is an αβ dimer that reversibly polymerizes into microtubules, which are long, hollow cylinders with an outer diameter of 25 nm. Several studies reveal an essential role in platelet biogenesis for β_1 tubulin, a divergent and lineage-specific β tubulin, which is a major component of the megakaryocyte proplatelet cytoskeleton and marginal microtubule coil of the platelet. β_1 Tubulin, which is expressed exclusively in platelets and megakaryocytes during the late stages of megakaryocyte development, is essential for the

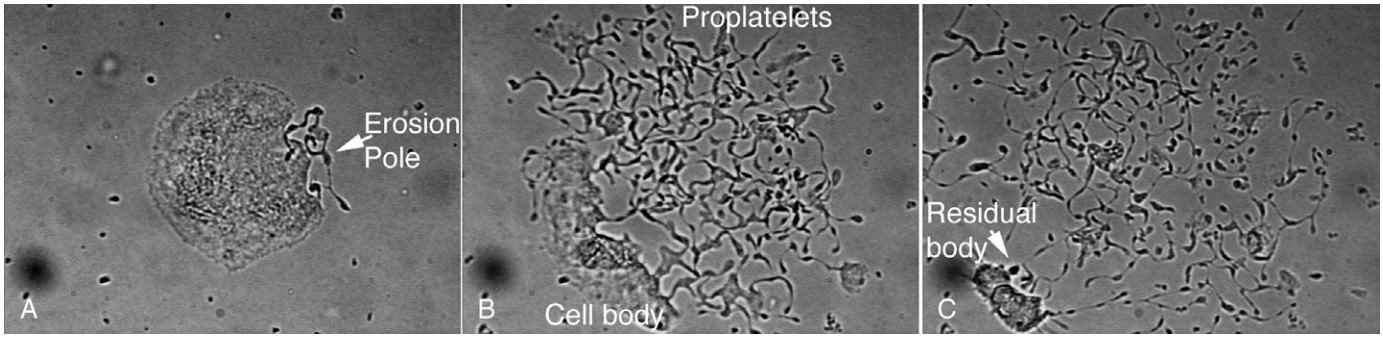

Figure 126-5 FORMATION OF PROPLATELETS BY A MOUSE MEGAKARYOCYTE. Time-lapse sequence of a maturing megakaryocyte showing the events that lead to elaboration of proplatelets in vitro. **A,** Platelet production begins when the megakaryocyte cytoplasm starts to erode at one pole *(arrow).* **B,** The bulk of the megakaryocyte cytoplasm has been converted into multiple proplatelet processes that continue to lengthen and form swellings along their length. These processes are highly dynamic and undergo bending and branching. **C,** Once the bulk of the megakaryocyte cytoplasm has been converted into proplatelets, the entire process ends in a rapid retraction that separates the released proplatelets from the residual cell body.

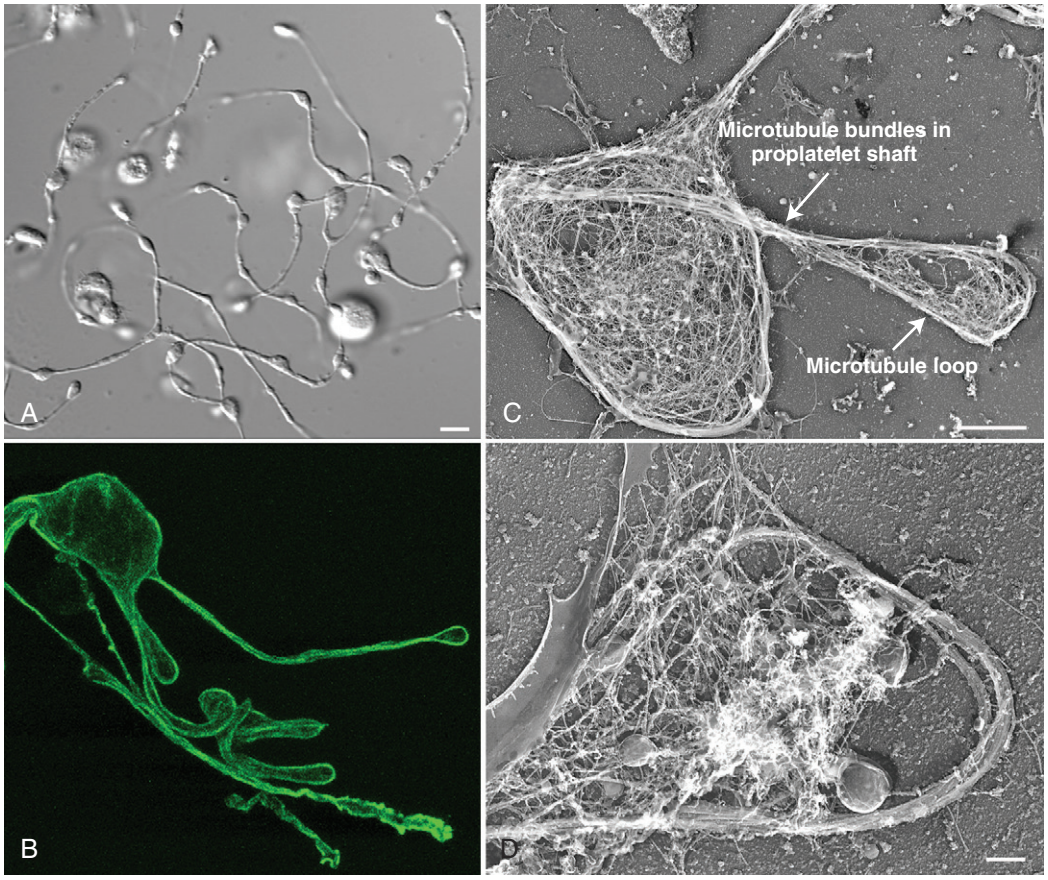

Figure 126-6 STRUCTURE OF PROPLATELETS. **A,** Differential interference contrast image of proplatelets elaborated by mouse megakaryocytes in culture (bar = 5 μm). **B,** Staining of proplatelets with Alexa 488 antitubulin IgG reveals that the microtubules line the shaft of the proplatelet and form loops at the proplatelet tips (bar = 5 μm). **C** and **D,** Organization of microtubules in the tips of proplatelets. **C,** Microtubules form bundles in the proplatelet shafts (bar = 2 μm). **D,** Microtubules loop in the proplatelet ends and reenter the proplatelet shafts (bar = 0.2 μm).

production of normal numbers of platelets, as well as for the discoid shape of platelets. The evidence supporting the role of β_1 tubulin in these processes comes from several sources. First, mRNA subtraction between wild type and NF-E2–deficient megakaryocytes demonstrates that β_1 tubulin is a downstream effector of the megakaryocyte transcription factor NF-E2 and is absent from NF-E2-deficient megakaryocytes. Second, genetic elimination of the β_1-tubulin gene in mice results in thrombocytopenia.[6] Third, megakaryocytes isolated from β_1-tubulin knock-out mice fail to form proplatelets in vitro and instead extend only a small number of blunt protrusions.

The first event that signals proplatelet production is the consolidation of microtubules into large bundles at the megakaryocyte cortex that subsequently are reorganized into parallel bundles in the shafts of the proplatelets (Fig. 126-6).[8] Microtubule bundles are thick near the body of the megakaryocyte as they enter the proplatelet shaft but become progressively thinner throughout the shaft, such that only 5 to 10 microtubules remain at the end of the proplatelet. Of note, the microtubule bundles that run down the proplatelet shaft make characteristic U turns in the tips and reenter the shaft, forming teardrop-shaped structures (Fig. 126-7). This creates a bipolar orientation of

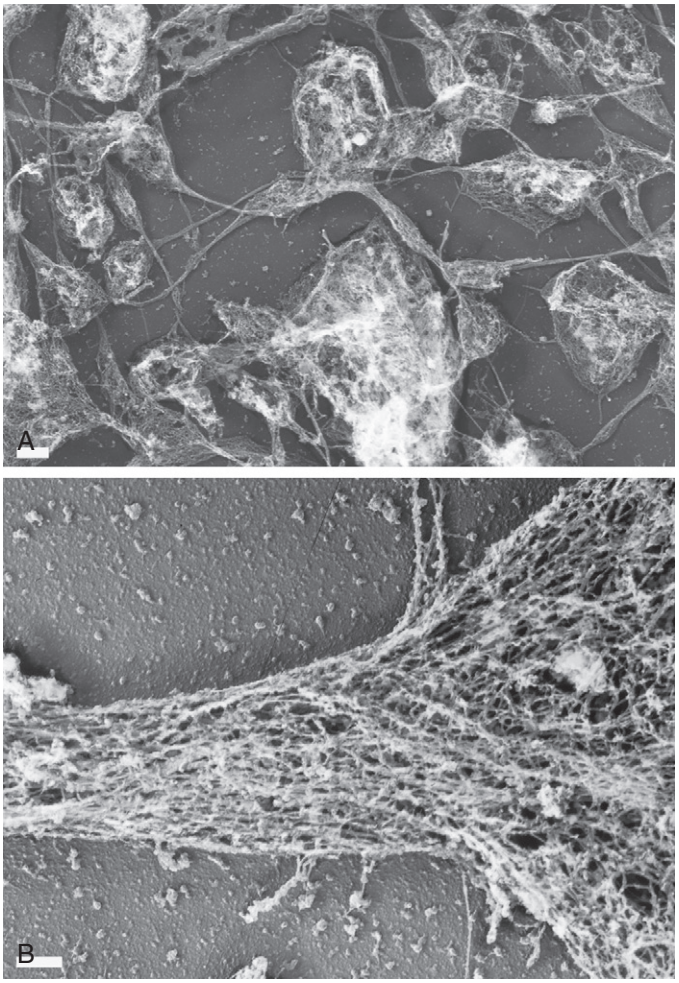

Figure 126-7 MEMBRANE SKELETON OF THE PROPLATELET. Representative electron micrographs of the detergent-insoluble proplatelet cytoskeleton. Proplatelets were permeabilized with 0.75% Triton X-100, 5 μM phallacidin, and 0.1% glutaraldehyde. Examination through electron microscopy reveals that the plasma membrane of the proplatelet tube is supported by a fibrous membrane skeleton that is similar in structure to the membrane skeleton of mature platelets. **A,** This low-magnification field shows that an intact membrane skeleton laminates the underside and extends along the entire length of proplatelets (bar = 1 μm). **B,** High magnification, three-dimensional electron micrograph of the proplatelet membrane skeleton demonstrating it to consist of a lattice-like network of elongated filamentous strands, similar in nature to the spectrin-based network in red blood cells and platelets. The membrane skeleton continuously laminates the underside of the proplatelet. A cytoplasmic bridge is shown *(left)* linking to a swelling *(right)* (bar = 200 nm).

bundles in the vicinity of the proplatelet tip, a geometry required to explain the bidirectional granule and organelle traffic observed in proplatelets. The looped arrangement of microtubules in proplatelet tips also constrains the elongation mechanism used to grow proplatelets because of an insufficient number of free microtubule ends to nucleate this reaction.

Direct visualization of microtubule dynamics in living megakaryocytes using green fluorescent protein (GFP) technology has provided insights into how microtubules orient to power proplatelet elongation (see Fig. 126-4, *A* and *B*). End-binding protein 3 (EB3), a microtubule plus end-binding protein associated only with growing microtubules, fused to GFP was retrovirally expressed in murine megakaryocytes and used as a marker to locate microtubule plus ends and to follow plus end dynamics.[7] Immature megakaryocytes without proplatelets use a centrosomal-coupled microtubule nucleation/assembly reaction, which appears as a prominent starburst pattern when visualized with EB3-GFP. Microtubules assemble only from the centrosome and grow outward into the cell cortex, where they turn and run parallel to the cell edges. Just before proplatelet production begins, however, centrosomal assembly ends and microtubules release and consolidate into the cortex as bundles. Fluorescence time-lapse microscopy of living, proplatelet-producing megakaryocytes expressing EB3-GFP reveals that as proplatelets elongate, microtubules assemble continuously throughout the entire proplatelet. EB3-GFP studies also reveal that microtubules polymerize in both directions in proplatelets—that is, toward both the tips and cell body, demonstrating that microtubules composing the bundles have a mixed polarity. The cytoplasmic Ran-binding protein, RanBP10, is a β_1-tubulin binding protein that appears to regulate the assembly of proplatelet microtubules.[9] Even though microtubules are continuously assembling at their plus ends in proplatelets, polymerization per se does not provide the force for proplatelet elongation. First, the rates of microtubule polymerization (average 10.2 μm/min) are approximately 10-fold faster than the proplatelet elongation rate. Second, proplatelets elongation continues when microtubule polymerization is blocked with drugs that inhibit net assembly, suggesting an alternative mechanism for proplatelet elongation. Third, proplatelets possess an inherent microtubule sliding mechanism. Cytoplasmic dynein, a minus-end microtubule molecular motor protein, localizes along the microtubules of the proplatelet and appears to directly contribute to microtubule sliding because inhibition of dynein through disassembly of the dynactin complex prevents proplatelet formation. Microtubule sliding can be reactivated in detergent-permeabilized proplatelets. Adenosine triphosphate, known to support the enzymatic activity of microtubule-based molecular motors, activates elongation in permeabilized proplatelets that contain dynein and its regulatory complex dynactin. Thus dynein-facilitated microtubule sliding appears to be the key event driving proplatelet elongation.

Nascent platelets assemble at the bulbous ends of proplatelets as defined by the rolling of a single microtubule into a coil having the same diameter as the coil found in the mature platelet. Given that maturation of the platelet is limited to these sites, efficient platelet production requires a large number of proplatelet ends. Megakaryocytes use a unique mechanical process to repeatedly bifurcate the shafts of the proplatelet, thereby amplifying the number of ends. To accomplish this task, the shaft of elongating proplatelets is bent on itself and a new proplatelet grows out of the bend; a process that results in bifurcation of the shaft. Whereas proplatelet elongation is mediated by microtubules, actin mediates the bending and branching of proplatelet shafts. Actin filament assemblies decorate branch points, and agents that disrupt actin assembly, such as the cytochalasins, abolish proplatelet branching. One possibility is that proplatelet bending and branching are regulated by the actin-based molecular motor myosin. Myosin II is an ATPase motor that makes up 2% to 5% of the total platelet protein. Myosin II binds to actin filaments and generates force for contraction. Each myosin has two heads and a long, rod-like tail whose function is to permit the molecules to assemble into bipolar filaments. Of interest, a mutation in the tail domain of the nonmuscle myosin heavy chain A gene in humans results in several disorders, including May-Hegglin anomaly, Sebastian syndrome, and Fechtner syndrome. These rare autosomal platelet disorders are characterized by thrombocytopenia with giant platelets. Recent findings have implicated myosin IIA in restricting proplatelet production until megakaryocytes attain full maturity. The loss of myosin IIA function through targeted gene disruption in mice, through dominant inhibitory mutations in humans, or by manipulation of cultured megakaryocytes appears to accelerate proplatelet production. Consequently, platelet production is inefficient and produces platelets that vary extensively in shape, content, and diameter. These findings also suggest that the Rho-ROCK-myosin light chain pathway regulates myosin IIA.

In addition to playing an essential role in proplatelet elongation, the microtubules lining the shafts of proplatelets serve a secondary function: transport of membrane, organelles, and granules into

proplatelets and assembling platelets at proplatelet ends (see Fig. 126-4, *C*). Organelles are sent individually from the cell body into the proplatelets, where they move bidirectionally until they are captured at proplatelet tips.[14] Immunofluorescence and electron microscopic studies indicate that organelles are intimately associated with microtubules, and actin poisons do not diminish organelle motion. Thus movement appears to involve microtubule-based forces. Bidirectional organelle movement is conveyed in part by the bipolar arrangement of microtubules within the proplatelet because kinesin-coated latex beads move in both directions over the microtubule arrays of permeabilized proplatelets. Of the two major microtubule motors, kinesin and cytoplasmic dynein, only the plus end-directed kinesin is localized in a pattern similar to organelles and granules and is likely responsible for transporting these elements along microtubules. It appears that a twofold mechanism of organelle and granule movement occurs in platelet assembly: first, organelles and granules travel along microtubules, and second, the microtubules themselves slide bidirectionally in relation to other motile filaments, indirectly moving organelles along proplatelets in a piggyback manner.

Although the roles of microtubules and actin filaments in proplatelet development have been extensively studied, our understanding of the function of the membrane skeleton has only recently been established. High-resolution electron microscopy reveals that proplatelets have a dense spectrin-based membrane skeleton similar in structure to that of mature blood platelets. Nonerythroid spectrin subunits, alpha-II and beta-II spectrin, are predominately expressed in mouse megakaryocytes, proplatelets, and platelets, but erythroid alpha-I and beta-I spectrin isoforms are also expressed (see Fig. 126-6).[15] Assembly of spectrin tetramers is required for development of the demarcation membrane system and proplatelet elaboration, because expression of a spectrin tetramer–disrupting construct in megakaryocytes inhibits both processes. Furthermore, integration of this spectrin-disrupting construct into a permeabilized proplatelet system quickly destabilizes proplatelets, resulting in massive blebbing and swelling. Spectrin tetramers also stabilize the barbell-like shapes of the penultimate stage in platelet production (see later). Taken together, these studies suggest a role for spectrin in different steps of megakaryocyte development through its participation in the formation of demarcation membranes and in the maintenance of proplatelet structure.

Platelet Maturation at the Proplatelet Tip

Platelet maturation at proplatelet tips finalizes when a single microtubule detaches from the microtubule bundle and is rolled into a coil. To complete construction of mature platelets, once the fundamental cytoskeletal components have been delivered to and assembled in the platelet buds, the buds must fill with their organelle and granule content.

Granules are sent to nascent platelets on the microtubule tracks of the proplatelets. The concentration of this cargo in the platelet occurs by an end-trapping mechanism as granules and organelles, which enter the nascent platelet, continue to move in the tip but do not return to the proplatelet shaft.

Release of Mature Platelets

Details of how mature platelets release from the proplatelet tips are beginning to come into focus. In vitro, maturation of proplatelets ends in a rapid retraction that separates a variable portion of the proplatelets from the residual cell body, leaving behind a naked, denuded nucleus (see Fig. 126-5, *C*). Activation of apoptotic pathways in the cell body has been shown to be coincident with this event. Junt and colleagues have used intravital fluorescence microscopy to visualize proplatelet production in the opened cranial marrow cavity of living mice.[16] Yellow fluorescent protein (YFP)–labeled megakaryocytes were seen to protrude proplatelets and release megakaryocyte fragments into the marrow sinusoids of living mice. Notably, these anucleate fragments typically exceed platelet dimensions, suggesting that platelet morphogenesis continues in the circulation. In line with these observations, we have recently identified a previously unrecognized intermediate stage in platelet formation and release, which we termed the *preplatelet*.[17] Preplatelets are defined as discoid cells (3 to 10 microns) that retain the capacity to convert into barbell-shaped proplatelets and undergo fission into platelets. The conversion of preplatelets to barbell proplatelets is powered by microtubule-based forces. It is likely that the microtubule motors that drive proplatelet extension are involved in aspects of platelet release, as well as in the process of microtubule coiling. Sliding of an uncoiled portion of the microtubule relative to the rigid microtubule bundle in the proplatelet tip would provide a simple mechanism to effect platelet release and would explain the variable morphology of a small but reproducible percentage (<5%) of dumbbell-shaped platelets that are present in blood. Recently, it was demonstrated that individual human platelets have the innate capacity to duplicate and form new cell bodies that undergo fission into platelets.[18] The morphologic similarities between platelets that form new cell bodies and preplatelets are striking. Whether or not newly released platelets exhibit a preplatelet phenotype, which allows them to form barbell-shapes and divide again, is not clear.

Location of Platelet Release

Megakaryocytes are produced in the bone marrow, and some undergo fragmentation into platelets in this location. It has been suggested that, by extending into the bone marrow sinusoids, proplatelets provide a mechanism for extension into the bone, allowing release of platelets directly into the circulation.[19,20] Megakaryocytes have been identified in intravascular sites within the lung, leading to a theory that some platelets are formed from their parent cell in the pulmonary circulation.

Transcriptional Regulation of Platelet Formation

Megakaryocyte development and platelet formation are controlled by the coordinated action of transcription factors that specifically turn on the genes of megakaryocyte precursors or suppress the expression of genes that support other cell types.[21] Gene-targeting studies in mice have identified several genes that are crucial for megakaryocyte development and platelet formation. Leading the list of transcription factors that play an essential role in megakaryocyte maturation and platelet biogenesis is the basic leucine zipper heterodimer NF-E2. NF-E2 is a protein composed of a ubiquitously expressed 18- to 20-kd small-Maf subunit and a p45 subunit that is restricted to erythroid and megakaryocytic lineages. Although NF-E2 was postulated to be a transcription factor that specifically drove the expression of genes essential for erythropoiesis, mice lacking p45 NF-E2 do not exhibit defects in erythropoiesis. Instead, mice deficient in the p45 subunit or two of the small-Maf subunits die of hemorrhage shortly after birth because of a complete lack of circulating platelets. Although megakaryocytes undergo normal endomitosis and proliferate in response to Tpo, mice deficient in p45 NF-E2 produce increased numbers of megakaryocytes that are larger than normal, contain fewer granules, exhibit a highly disorganized DMS, and fail to generate proplatelets in vitro, a phenotype indicative of a late block in megakaryocyte maturation. Therefore NF-E2 appears to control the transcription of a limited number of genes involved in cytoplasmic maturation and platelet formation. Shivdasani and colleagues generated a subtracted cDNA library enriched in transcripts downregulated in NF-E2 knock-out megakaryocytes. Using this approach, these investigators have started to identify the downstream targets of NF-E2 and analyzed their role in the terminal stages of megakaryocyte differentiation. Putative transcriptional targets of NF-E2 include β_1 tubulin, thromboxane synthase, and proteins that regulate inside-out signaling via $\alpha_{IIb}\beta_3$ integrin. The zinc finger protein GATA1 is also a transcription factor that plays a critical role in driving the

expression of genes essential for megakaryocyte maturation. However, unlike NF-E2, which appears to drive the later stage of megakaryocyte development, GATA1 functions at multiple stages of development. Initially, GATA proteins were thought to regulate red blood cell maturation because genetic disruption of the GATA1 gene in mice results in embryonic lethality because of a block in erythropoiesis. However, several more recent observations also implicate GATA1 as a regulator of megakaryocyte differentiation. First, forced expression of GATA1 in the early myeloid cell line 416b induces megakaryocyte differentiation. Second, Shivdasani and colleagues used targeted mutagenesis of regulatory elements within the GATA1 locus to generate mice with a selective loss of GATA1 in the megakaryocyte lineage. These knockdown mice expressed sufficient levels of GATA1 in erythroid cells to circumvent the embryonic lethality caused by anemia. GATA1 deficiency in megakaryocytes leads to severe thrombocytopenia. Platelet counts are reduced to approximately 15% of normal, and the small number of circulating platelets are round and significantly larger than usual. These mice have increased numbers of small megakaryocytes that exhibit an accelerated rate of proliferation. The small cytoplasmic volume of GATA1-deficient megakaryocytes typically contains an excess of rough endoplasmic reticulum, very few platelet-specific granules, and an underdeveloped or disorganized DMS, suggesting that maturation of megakaryocytes is arrested in GATA1-deficient megakaryocytes.

A family with X-linked dyserythropoietic anemia and thrombocytopenia due to a mutation in GATA1 has been described. A single nucleotide substitution in the amino-terminal zinc finger of GATA1 inhibits the interaction of GATA1 with its essential cofactor, friend of GATA1 (FOG). Although megakaryocytes in affected family members are abundant, they are unusually small and exhibit several abnormal features, including an abundance of smooth endoplasmic reticulum, an underdeveloped DMS, and a lack of granules. These observations suggest an essential role for the FOG1-GATA1 interaction in thrombopoiesis. Genetic elimination of FOG in mice unexpectedly resulted in specific ablation of the megakaryocyte lineage, suggesting a GATA1-independent role for FOG in the early stages of megakaryocyte development; GATA1 and FOG are required for megakaryocyte generation from a common bipotential progenitor.

Several knock-out mice also indicate a role for additional transcription factors in megakaryocyte development. Mice carrying a null mutation in Fli-1, a member of the ETS family of winged helix-turn-helix transcription factors that bind purine-rich sequences in gene promoters, exhibit defects in megakaryocyte development. Megakaryocytes cultured from mice lacking Fli-1 contain reduced numbers of α-granules, disorganization of the demarcation membranes, and a reduction in size. Mice lacking the hematopoietic zinc finger (Hzf) protein, a transcription factor that is predominantly expressed in megakaryocytes, have reduced numbers of α-granules in megakaryocytes and platelets. Therefore Hzf may regulate the transcription of genes involved in the synthesis of α-granule components and/or their packaging into α-granules. SCL, a basic helix-loop-helix transcription factor initially identified in a subset of human T-cell leukemia with multilineage characteristics, also appears to be critical for megakaryopoiesis. Deletion of SCL in mice indicates this transcription factor is required for proper erythroid and megakaryocyte development.

PLATELETS

Structure of the Resting Platelet

Megakaryocyte development culminates in the release of mature discoid platelets having dimensions of approximately 3.0 × 0.5 μm and a cytoplasmic volume of 7 fL.[22] The evolutionary explanation for the discoid shape of the platelet is unknown. Discoid shape may permit more efficient flow or dispersion of clot-promoting elements or may simply reflect the microtubule-based mechanism by which platelets are produced. In humans, platelets, once released from the ends of proplatelets, normally circulate for 7 to 10 days. Given that nearly 1 trillion platelets circulate in an adult human, each day an adult produces approximately 100 billion platelets.

The precise morphology of newly released platelets is unknown. However, when released into the circulation or maintained in culture, platelets have a very reproducible structure. Although they are heterogeneous in size, presumably because of changes in size as they age, platelets have discoid shapes with flat, featureless surfaces (Fig. 126-8, *A,* and Fig. 126-9, *A*) that are interrupted only by pit-like openings into the open canalicular system (OCS). The OCS is an extensive system of internal membrane conduits that serves as a passageway to the outside world into which granular contents are released. It also is a reservoir of plasma membrane, membrane receptors, and proteins. For example, approximately 30% of the thrombin receptors are localized in the OCS of the resting platelet, awaiting movement to the surface when the cells are activated. Although contiguous with the plasma membrane, not all proteins on the cell surface can enter the OCS. Factors controlling movement into the OCS remain to be defined but likely depend on the actin cytoskeleton. Entry restriction, however, occurs at the necks of OCS infoldings. The third function of the OCS is to serve as a source of redundant plasma membrane for cell spreading. OCS membrane initially is disgorged to the surface following cell activation. When cells are activated in solution, much of this membrane is subsequently reabsorbed into the remnants of the OCS.

A small thin zone of cytoplasm separates the plasma membrane of the resting platelet from a marginal microtubule coil and the general intracellular space, which contains all inclusion bodies and the internal cytoskeleton of the cell. This zone is filled with the spectrin-based membrane skeleton (see Fig. 126-9, *A*). Beneath this zone sits a microtubule coil. Then follows the cytoplasmic space, which is filled with filaments of actin that embed granules, organelles, the OCS, and other specialized membrane systems such as smooth endoplasmic reticulum.

Platelets actively recruit other blood-borne cells to areas of vascular damage by releasing mediators packaged in intracellular granules (described earlier in Cytoplasmic Maturation) that initiate secondary homeostatic interactions and that express a "sticky" apical surface after the platelets adhere. In the resting platelet, granules are juxtaposed together and are in intimate association with the membranes of the OCS. The release reaction of platelet granules differs from that of other cells. Granules rarely fuse with the plasma membrane; instead they exocytose into the OCS. Platelets also contain lysosomes and a few mitochondria, which are easily identified under the electron microscope by their internal system of membrane cristae.

Cytoskeleton of the Resting Platelet

Although both microtubule- and actin-based forces have been considered in the elaboration and branching of proplatelets, respectively, it is the integration of the microtubule and actin cytoskeletal elements that uniquely defines the shape of the mature platelet. One of the most distinguishing features of the resting platelet is its marginal microtubule coil (see Fig. 126-8). αβ-Tubulin dimers assemble into microtubule polymers under physiologic conditions. In resting platelets, tubulin is equally divided between dimer and polymer fractions. In many cell types, αβ-tubulin subunits are in a dynamic equilibrium with microtubules such that reversible cycles of assembly-disassembly of microtubules are observed. Microtubules are long, hollow polymers (24 nm in diameter) that are responsible for many types of cellular movements, such as segregation of chromosomes during mitosis and transport of organelles across the cell. The microtubule ring of the resting platelet, initially characterized in the late 1960s by White and Krivit, was described as a single microtubule approximately 100 μm long and is coiled 8 to 12 times inside the periphery of the platelet. However, recent work suggests that the marginal band is highly dynamic and consists of multiple microtubules with mixed polarity that undergo constant assembly and disassembly.[23] This may accommodate the shrinkage of microtubule coil diameters that occurs

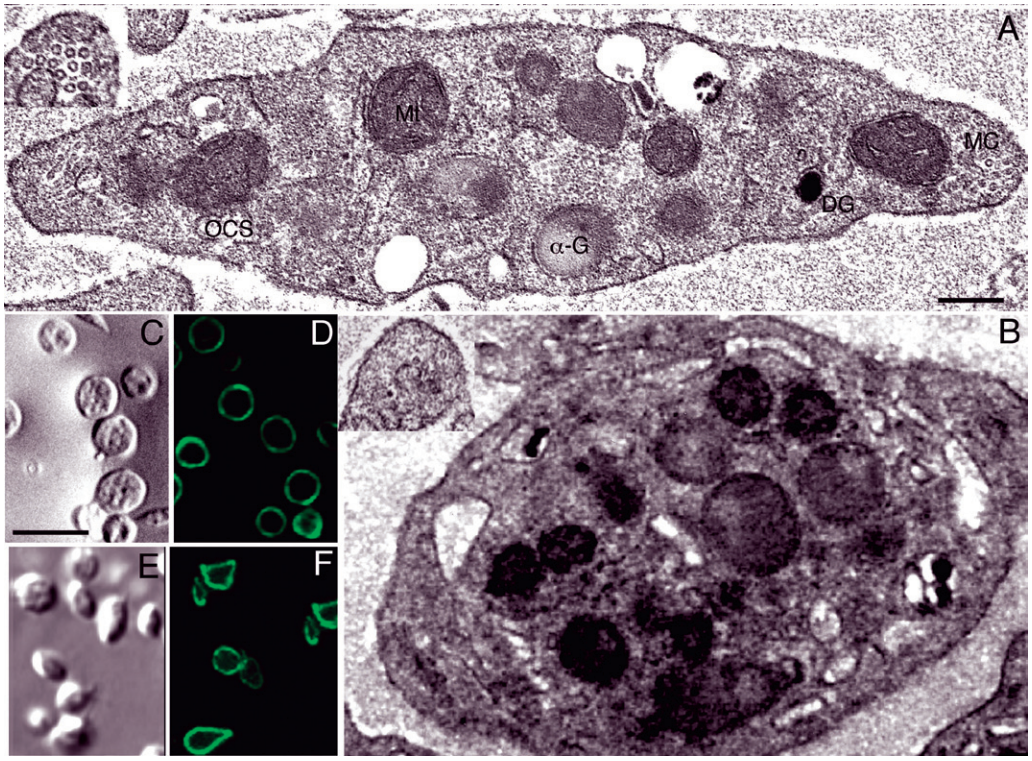

Figure 126-8 STRUCTURE OF NORMAL MOUSE PLATELETS (**A, C, D**) COMPARED WITH PLATELETS LACKING β_1 TUBULIN (**B, E, F**). **A,** Electron micrograph of a resting mouse platelet. This platelet was sectioned through its thin axis. The cut plane reveals the microtubule coil (MC) at the cell periphery. The inset shows a high-magnification cross-section through the microtubule coil of the resting platelet. The microtubule is wound 11 times in this platelet, forming the coil. The cytoplasmic space embeds mitochondria (MT), α-granules (α-G), and dense granules (DG). The spaces created by the open canalicular system (OCS) are apparent. **B,** Electron micrograph of a thin section through a platelet isolated from a mouse lacking β_1 tubulin (bar = 0.2 μm). Platelets from these animals are spherical **(E)** and have only a rudimentary microtubule coil *(inset)*. In this platelet the microtubule is twisted twice. **C,** Differential interference contrast image of resting platelets shows them to be flat discs. **D,** Microtubule coil of the resting mouse platelet. Staining of fixed mouse platelets with Alexa 488 antitubulin IgG reveals the microtubule coil. This coil resides at the periphery of the platelet. **E,** Differential interference contrast image of platelets lacking β_1 tubulin. **F,** Staining of fixed mouse β_1-tubulin–deficient platelets with Alexa 488 antitubulin IgG reveals the coil is defective and bent in a number of places throughout the platelets. (**C** through **F** are the same magnification; bar = 5 μm.)

with aging of platelets. The primary function of the microtubule coil is to maintain the discoid shape of the resting platelet. Disassembly of platelet microtubules with drugs such as vincristine, colchicine, or nocodazole causes platelets to become round and to lose their discoid shape. Cooling the platelets also causes disassembly of the microtubule coil and loss of the discoid shape. Mice lacking β_1 tubulin, the major hematopoietic β-tubulin isoform, produce platelets that lack their characteristic discoid shapes and have defective marginal bands. Genetic elimination of β_1 tubulin in mice results in thrombocytopenia with circulating platelet counts below 50% of normal. β_1-Tubulin–deficient platelets are spherical in shape, apparently due to shortened marginal bands with fewer coilings. Whereas normal platelets possess a marginal band that consists of 8 to 12 coils, β_1-tubulin knock-out platelets contain only 2 to 3 coils. A human β_1-tubulin functional substitution (AG→CC) inducing both structural and functional platelet alterations has been described. Of note, the Q43P β_1-tubulin variant was found in 10.6% of the general population and in 24.2% of 33 unrelated patients with undefined congenital macrothrombocytopenia. Electron microscopy revealed enlarged spherocytic platelets with a disrupted marginal band and structural alterations. Platelets with the Q43P β_1-tubulin variant showed mild platelet dysfunction, with reduced ATP secretion, thrombin receptor-activating peptide (TRAP)–induced aggregation, and impaired adhesion to collagen under flow conditions.[24] A more-than-doubled prevalence of the β_1-tubulin variant was observed in healthy subjects not undergoing ischemic events, raising the possibility that the variant confers an evolutionary advantage and a protective cardiovascular role.

Actin is the most abundant of all the platelet proteins, with 2 million molecules expressed per platelet. Of these molecules, 800,000 assemble to form the 2000 to 5000 linear actin polymers that exist in the resting cell (see Fig. 126-9, *A*). The remainder of the actin is maintained in storage as a 1 : 1 complex with β_4 thymosin, which can be converted to filaments during platelet activation to drive cell spreading. All evidence indicates that the filaments of the resting platelet are interconnected at various points into a rigid cytoplasmic network because platelets express high concentrations of actin cross-linking proteins, including filamin and α-actinin.[7] Both filamin and α-actinin are homodimers in solution. Three filamin genes are located on chromosomes 3, 7, and X. Filamin A (X) and filamin B (3) are expressed in platelets. Filamin A is expressed at more than 10-fold higher levels than is filamin B. Filamin subunits are elongated strands composed primarily of 24 repeats, each approximately 100 amino acids in length and folded into IgG-like β-barrels. Each strand has an amino-terminus actin-binding site that shares homology with other actin-binding proteins, two rod domains that are end-to-end assemblies of the repeat units, interrupted by two hinge domains between repeats 15 and 16, and 23 and 24, and a C-terminus self-association site (Fig. 126-10, *B*). Subunits assemble to form V-shaped bipolar molecules—that is, the self-association site is the vertex of the

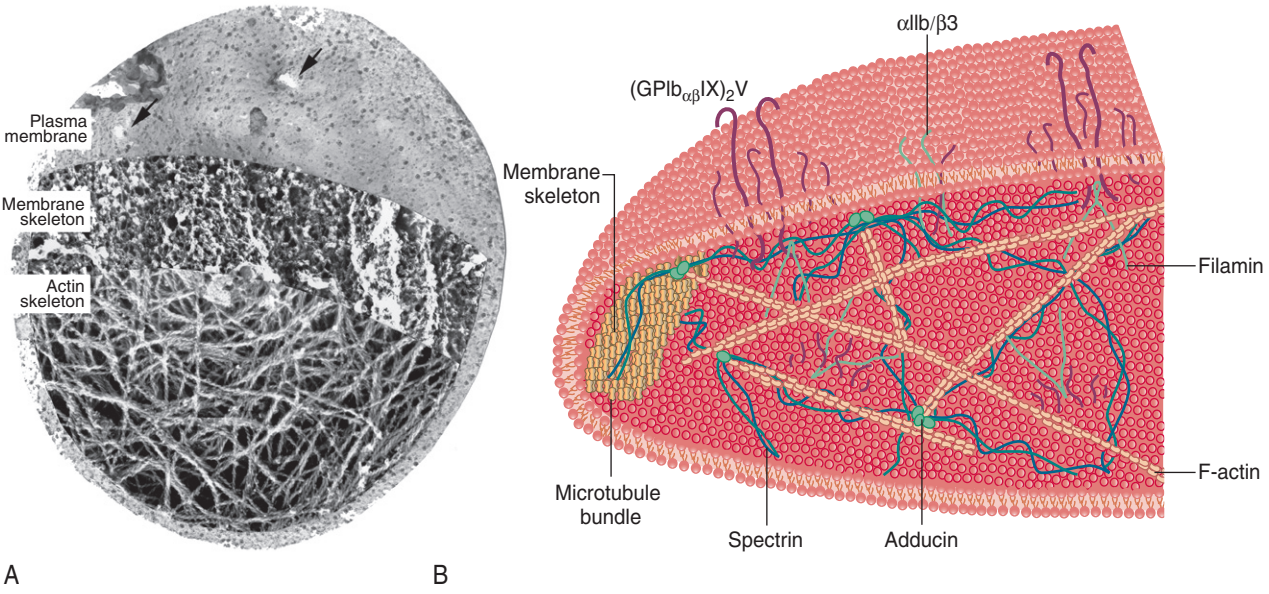

Figure 126-9 STRUCTURE OF THE RESTING HUMAN BLOOD PLATELET AND ITS ACTIN-BASED CYTOSKELETON. **A,** Composite illustrating the major actin cytoskeletal layers of the resting platelet. *Plasma membrane:* The plasma membrane of the resting cell is flat and featureless, except for periodic invaginations that lead into the open canalicular system (OCS) *(arrows). Membrane skeleton:* The plasma membrane of the platelet is supported by a submembranous spectrin-based skeleton. This network is composed primarily of spectrin molecules, which are tetramers with actin binding sites at the ends. Actin filament ends dock on spectrin to complete the network. The association between spectrin and F actin is promoted by adducin. *Actin cytoskeleton:* As discussed earlier, the spectrin network is both directly and indirectly attached to the underlying actin filaments. Filament ends interconnect spectrin molecules, whereas the filamin links run from the filament sides to the plasma membrane receptor $(GPIb_{\alpha\beta}IX)_2V$. The cytoplasmic space has a dense filling of actin filaments. Actin filaments from the cell center radiate outward. As the filaments approach the plasma membrane, they turn and run in parallel with it. The actin filaments have been decorated using myosin subfragment 1 (S1), which gives them a twisted cable-like appearance in frozen samples. Myosin S1 labeling reveals the polarity of the actin filament. "Pointed" and "barbed" ends are definable. The ends of actin filaments are bound by the ends of spectrin molecules on the edges of the membrane network *(arrowhead)*. A microtubule coil composed of a single long microtubule resides just beneath the plasma membrane at the periphery of the thin axis of the platelet (not shown) (bar = 0.5 μm). **B,** Schematic showing the structural features of the resting blood platelet cytoskeleton. Resting cells have discoid shapes. Structural elements that support this shape are (1) a marginal microtubule coil, (2) a spectrin-based membrane skeleton, and (3) a rigid network of cross-linked cytoplasmic actin filaments (only a small number of the actin filaments have been added to this illustration so that they will not obscure the rest of the structures in the cell). Platelets have a specialized membrane skeleton composed of spectrin, actin, and many associated proteins. Spectrin tetramers (200 nm long and 5 nm wide) have actin filament-binding sites at each molecular end. The membrane skeleton is held in compression between the plasma membrane and the cytoplasmic actin by filamin connections from the sides of actin filaments to the cytoplasmic tails of GPIbα subunit of the membrane glycoprotein complex that binds to von Willebrand factor $(GPIb\alpha\beta IX)_2V$ complex. Greater than 98% of the barbed ends of actin filaments are capped by adducin and capZ in the resting platelet.

V, and the actin-binding sites are on the free ends. Inclusion of the first hinge in filamin depends on alternative RNA splicing. Filamin now is recognized to be a prototype "scaffolding molecule" that collects binding partners and localizes them adjacent to the plasma membrane. Partners bound by filamin members include the small GTPases RalA, Rac, Rho, and Cdc42, with RalA binding in a GTP-dependent manner; the exchange factors Trio and Toll; kinases such as PAK1; phosphatases; and transmembrane proteins. Most partner proteins are bound within the C-terminus portion of filamin.

Central to the structural organization of the resting platelet is an interaction between filamin and the cytoplasmic tail of the GPIbα subunit of the GPIb-IX-V complex.[26] The second rod domain (repeat 17) of filamin has a binding site for the cytoplasmic tail of GPIbα. The interaction between filamin A and GPIbα occurs at the atomic level. Repeat 17 of filamin A has a groove between certain β-sheet strands that forms a pocket for the GPIbα tail (see Fig. 126-10). Binding between filamin A and GPIbα is driven by entropic forces, and the alignment and specificity are provided by large residues that create a lock-and-key fit between the two molecules. Whereas the interaction between one filamin A subunit and GPIbα has affinity of approximately 10 μM, high-affinity binding (10 nM) occurs when each filamin A subunit in a molecule and both GPIbα chains in a vWF receptor are engaged. Studies have shown that the bulk of platelet filamin (>90%) is in complex with GPIbα. This interaction has three consequences. First, it positions filamin's self-association domain and associated partner proteins at the plasma membrane while dangling filamin's actin binding sites into the cytoplasm. Second, because a large fraction of filamin is bound to actin, it aligns the GPIb-IX-V complexes on the surface of the platelet over the underlying filaments (see Fig. 126-9, *B*). Third, because the filamin linkages between actin filaments and the GPIb-IX-V complex pass through the pores of the spectrin lattice, it restrains the molecular movement of the spectrin strands in this lattice and holds the lattice in compression. The filamin-GPIbα connection is essential for the formation and release of discoid platelets by megakaryocytes; platelets lacking this connection are large and fragile and are produced in low numbers. However, the role of the filamin-vWF receptor connection in platelet construction is unknown. Because a low number of Bernard-Soulier platelets form and release from megakaryocytes, it can be argued that this connection is a late event in the maturation process and is not required for platelet shedding. Both filamin and GPIbα are synthesized early, but linkage between the two may not occur until later, perhaps as late as the final stages of platelet shedding.

Aside from the erythrocyte, the platelet is the only cell whose membrane skeleton has been visualized at high resolution. Like the

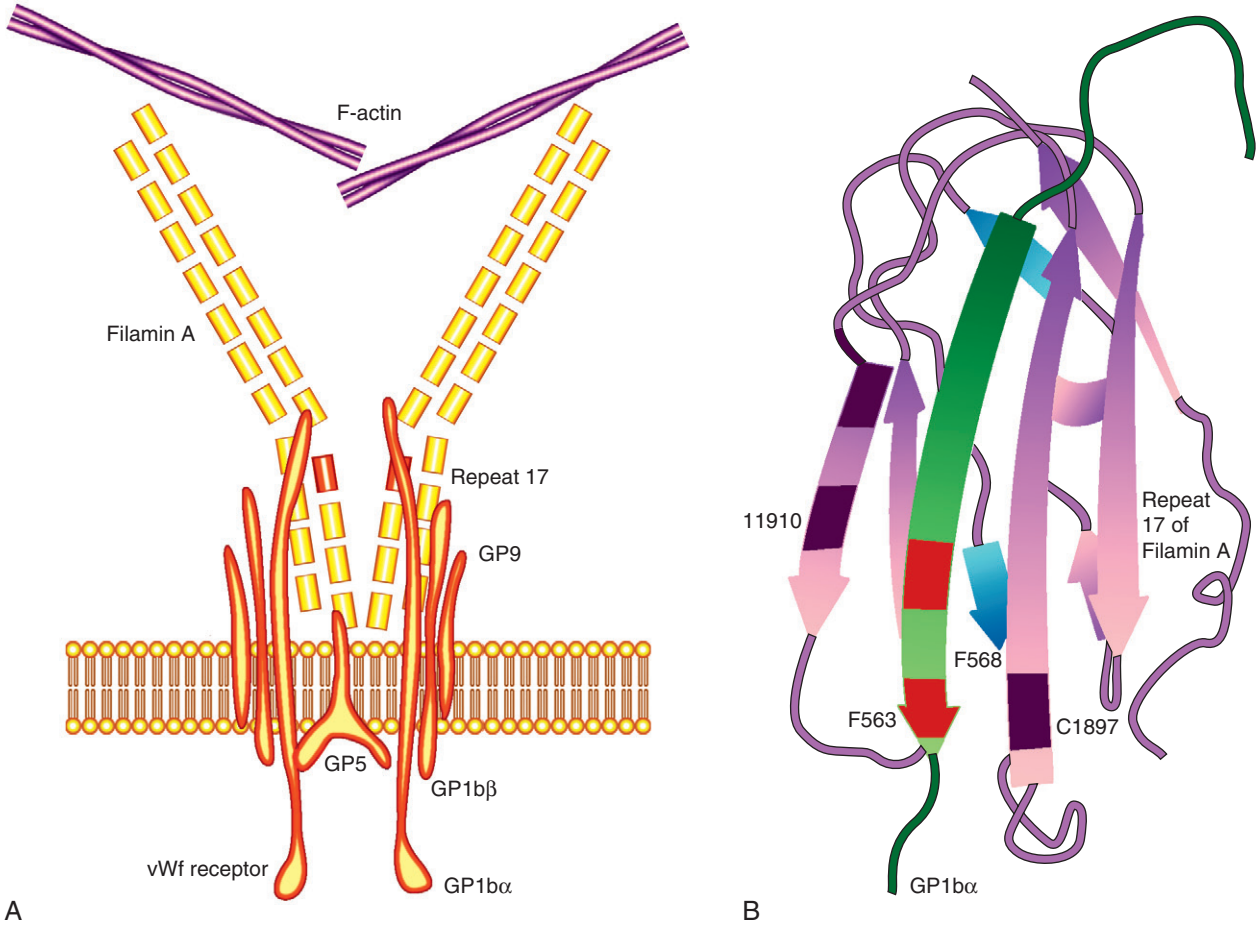

Figure 126-10 INTERACTION OF FILAMIN A WITH THE VON WILLEBRAND FACTOR RECEPTOR (vWFR). **A,** Model showing the orientation of filamin A when interacting with the GPIbα chain of the vWFR and cytoplasmic actin filaments. For tight binding of filamin A to vWFR, both GPIbα chains of the receptor must be engaged by a single filamin A molecule. **B,** Ribbon diagram showing the interface between filamin A repeat 17 and the filamin A binding region of the GPIbα tail (residues 556-577). Critical residues that provide the lock-and-key interaction between the two domains are indicated.

erythrocyte, the platelet membrane skeleton is a self-assembly of elongated spectrin strands (see Fig. 126-9) that interconnect through binding to actin filaments. Platelets express approximately 2000 spectrin molecules. Although considerably less is known about how the spectrin-actin network forms and is connected to the plasma membrane in the platelet relative to the erythrocyte, certain differences between the two membrane skeletons have been identified. First, the spectrin strands composing the platelet membrane skeleton interconnect using the ends of long actin filaments instead of short actin oligomers. These ends arrive at the plasma membrane originating from filaments in the cytoplasm. Hence the spectrin lattice is assembled into a continuous network by its association with actin filaments. Second, tropomodulins are not expressed at sufficiently high levels, if at all, to have a major role in capping the pointed ends of the platelet actin filaments. Instead, biochemical experiments have revealed that a substantial number (≈2000) of these ends are free in the resting platelet. Third, although little tropomodulin protein is expressed, α adducin and γ adducin are abundantly expressed and appear to cap many of the barbed ends of the filaments composing the resting actin cytoskeleton. Adducin is a key component of the membrane skeleton, forming a triad complex with spectrin and actin. Capping of barbed filament ends by adducin also serves the function of targeting them to the spectrin-based membrane skeleton, because the affinity of spectrin for adducin-actin complexes is greater than for either actin or adducin alone. Platelet glycoproteins involved in attaching spectrin to the membrane remain to be defined.

CHAPTER 127

MOLECULAR BASIS FOR PLATELET FUNCTION

Charles S. Abrams and Edward F. Plow

Platelets ordinarily circulate in blood vessels as individual cells that do not interact with other platelets or other cell types. A transition from this nonadhesive to an adhesive state can be rapidly initiated if platelets are exposed to a stimulatory agonist. A depiction of the platelet adhesive reactions that may be initiated in response to an injury to a blood vessel wall, as exemplified by rupture of an atherosclerotic plaque, is shown in Fig. 127-1. Disruption of the endothelial cell lining of the vessel exposes constituents within the subendothelial matrix, including a variety of adhesive proteins that can support initial platelet attachment. After attachment, platelets may undergo a spreading reaction that permits formation of multiple tight contacts between the cell surface and the matrix. These additional contacts may be critical for stabilizing the association of the platelets with the matrix in flowing blood. In conjunction with these adhesive reactions, the cells encounter agonists in the microenvironment that can trigger platelet secretion. The platelet secretory response results in the release of the contents of intracellular storage granules. Granule constituents include substances, such as adenosine diphosphate (ADP), that can stimulate circulating platelets and endow them with new adhesive properties. Stimulated platelets interact with one another during platelet aggregation to form an effective plug that seals the injured vessel wall and prevents excessive blood loss. This series of platelet responses—attachment, spreading, secretion, and aggregation—is essential for the hemostatic function of platelets. However, if these same events occur on an injured endothelial cell or on the surface of a disrupted atherosclerotic plaque, they can lead to the formation of an occlusive platelet-rich thrombus. At the other extreme, abnormalities in platelet adhesive reactions of either a genetic (e.g., Glanzmann thrombasthenia or Bernard-Soulier syndrome) (see Chapters 132 and 133) or an acquired origin (e.g., drug induced thrombocytopenia) (see Chapters133 and 135) can result in bleeding. Thus, platelet adhesive reactions and secretion are central events in health and disease processes; bleeding, hemostasis, and thrombosis are in delicate balance and are regulated by these platelet functions.

This chapter addresses the molecular basis of platelet adhesive reactions and secretory responses. Great strides have been made in defining the mechanisms that govern these functional responses. At the heart of these platelet responses are ligand–receptor interactions. Indeed, the platelet has often served as a model cell type for studying ligand–receptor interactions and establishing basic mechanisms of cell adhesion and secretion.

MOLECULAR BASIS OF PLATELET ADHESION

Studies in vitro, particularly under flow conditions (i.e., in closed chambers that permit whole blood or isolated components to flow across a selected matrix at selected shears) and in vivo studies using transgenic mouse models in which specific molecules have been deleted, mutated, or overexpressed illustrate the complexity of the reactions leading to thrombus formation, growth, and stabilization. For simplicity, we have dissected these events, but in reality, they occur rapidly and in an overlapping fashion.

Substrates for Platelet Attachment and Spreading

Some of the major subendothelial matrix proteins that support platelet attachment or spreading reactions are listed in Table 127-1. From the extent of this list, it is clear that the platelet can adhere to a variety of substrates when the endothelium is disrupted. To maintain hemostasis, the endothelium must create an effective barrier that prevents circulating platelets from reaching the matrix and initiating thrombus formation. In addition to serving as a physical barrier, endothelial cells synthesize and elaborate components, such as prostaglandin I_2, nitric oxide, and enzymes (CD39/CD73) that are involved in metabolism of ADP. These components prevent platelet activation and impart a nonthrombogenic character to the normal endothelium (see Chapter 129).

Studies of mice deficient in individual matrix proteins have documented that multiple adhesive proteins are involved in the formation, growth, and stabilization of platelet-rich thrombi.[1-4] Several considerations affect the role of individual matrix constituents in mediating platelet adhesion:

1. Not all of the adhesive proteins listed in Table 127-1 support the same spectrum of platelet adhesive responses. For example, under some conditions, platelets attach to, but do not spread on, laminin,[1] but von Willebrand factor (vWF) and fibronectin support cell attachment and spreading.[5-8] Collagen not only supports the attachment and spreading of platelets but can also induce a secretory response.[9] Of the multiple forms of collagen, types I, III, and VI are particularly important in supporting platelet adhesion.
2. A wealth of evidence indicates that the phenotypic properties of endothelial cells from different blood vessels vary and that the composition of the subendothelial matrix also varies. Even within the same vessel, the characteristics of its endothelial cells may differ. Areas of turbulent flow, which occur at bifurcations of vessels, are prone to development of atherosclerotic lesions, and shear-responsive elements in the promoters of certain genes can lead to changes in the expression of endothelial proteins[10,11] and alterations in their adhesive properties.[12,13] Thus, particular proteins may play a dominant role in supporting platelet adhesion in certain blood vessels.
3. Shear rate in flowing blood, which varies depending on vessel caliber, influences platelet adhesion. Shear is particularly important in defining the contribution of vWF to platelet adhesion. Patients with von Willebrand disease (see Chapter 140) have a bleeding diathesis, attesting to the importance of vWF in supporting platelet function. However, in vitro experiments demonstrate a role for vWF in platelet adhesion at high but not at low shear rates.[6,14,15] By contrast, fibronectin plays a role in platelet adhesion both high and low shear rates.[16,17] Despite these differences, both proteins have been implicated in thrombus formation.[4,14]
4. Many adhesive proteins interact with each other. For example, vWF, fibronectin, and thrombospondin all bind to collagen,[18-20] although they exhibit variable reactivity depending on the collagen

Table 127-1 Some of the Major Subendothelial Matrix Constituents That Support Platelet Adhesion

Matrix Constituent	Comment
Collagens	Large family of proteins with certain members supporting platelet adhesion, aggregation, and secretion
von Willebrand factor	Large multimeric protein critical for the hemostatic function of platelets
Fibronectin	Dimeric or multimeric protein that supports attachment and spreading of platelets
Thrombospondin-1	Trimeric protein exhibiting both adhesive and antiadhesive properties
Laminins	Proteins supporting platelet attachment
Microfibrils	A fibular bundle of protein constituents found in certain matrices

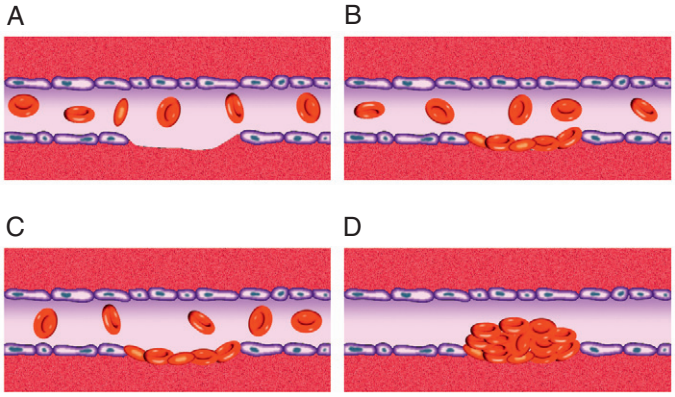

Figure 127-1 HEMOSTATIC RESPONSE OF PLATELETS TO INJURY. **A,** Disruption of the endothelial cell lining of the blood vessel exposes constituents of the subendothelial matrix. **B,** Platelets attach to and spread on matrix constituents. **C,** Platelet secretion may be initiated. **D,** Released platelet constituents can activate additional platelets, which aggregate with one another to form a thrombus.

types. These interactions may bridge platelets to matrix proteins or they may modulate the adhesive properties of a matrix protein.

5. Several of the adhesive proteins are found in platelet secretory granules or in plasma, as well as being matrix constituents. Whereas vWF and fibronectin are present in all three locations, thrombospondin is a major platelet granule constituent.[21,22] Proteins from all three sources—the matrix, the platelet, and the plasma—contribute to platelet adhesion. The adhesive proteins derived from each of these sources may be functionally distinct because they are not structurally identical. For example, the extent of vWF and fibronectin multimerization differs between molecules derived from plasma and those of the matrix. With fibronectin, the splice forms of molecules derived from plasma are different from those in platelets.[23]
6. Matrix proteins are subject to degradation by a variety of proteolytic enzymes. Such proteolysis can modulate the adhesive properties of the matrix proteins. In some cases, degradation exposes cryptic adhesive sequences that can interact with additional platelet adhesion receptors.[24,25]

Overall, the subendothelial matrix should be viewed as a dynamic and mutable interface that provides multiple substrates to support platelet adhesion.

Table 127-2 Platelet Receptors for Adhesive Proteins

Ligand	Receptor(s)	Other Common Designations
Collagen	GPIa-IIa, $\alpha_2\beta_1$ GPIIb-IIIa, $\alpha_{IIb}\beta_3$ GPIV GPVI	VLA-2 GPIIIb, CD36
Fibrinogen	GPIIb-IIIa, $\alpha_{IIb}\beta_3$ Vitronectin receptor, $\alpha_v\beta_3$	
Fibronectin	GPIc-IIa, $\alpha_5\beta_1$ GPIIb-IIIa, $\alpha_{IIb}\beta_3$	VLA-5
Thrombospondin	Vitronectin receptor, $\alpha_v\beta_3$ GPIV Integrin-associated protein	GPIIIb, CD36 IAP
Vitronectin	Vitronectin receptor, $\alpha_v\beta_3$ GPIIb-IIIa, $\alpha_{IIb}\beta_3$	
von Willebrand factor	GPIb-V-IX GPIIb-IIIa, $\alpha_{IIb}\beta_3$	
Laminin	GPIc-IIa region, $\alpha_6\beta_1$	VLA-6

Platelet Adhesion Receptors

The individual adhesive proteins serve as ligands for specific receptors on the platelet surface (Table 127-2). Because several nomenclature systems have been used to identify the membrane proteins of the platelet, the same receptor may have multiple designations. One of the most widely used systems designates the membrane proteins according to their electrophoretic mobility on polyacrylamide gels. Under these conditions, higher-molecular-weight proteins migrate more slowly. Separation by this technique gives rise to glycoprotein (GP) I, II, III, and so on, with GPI having the highest molecular weight. With more discriminating gel systems, additional proteins were identified in the GPI position, hence GPIa, GPIb, and GPIc, and so forth.[26] Even these distinctions require further refinement; for example, there are at least three distinct polypeptides in the GPIc position. Several of the membrane proteins on the platelet surface exist as noncovalent complexes; thus, GPIb-V-IX-V, GPIc-IIa, and GPIIb-IIIa can be regarded as single-membrane proteins. Because several of these membrane proteins are members of the integrin family of adhesion receptors (see later discussion), the integrin nomenclature is often used. For example, GPIc-IIa is referred to as $\alpha_5\beta_1$ and GPIIb-IIIa as $\alpha_{IIb}\beta_3$. Other nomenclature systems have arisen from the fact that several platelet membrane proteins are also found on the surface of other cell types where they have been assigned different names. This forms the basis of the VLA (very late antigens) designations for some platelet membrane proteins. Likewise, certain proteins may also have extracellular matrix (ECM) or leukocyte differentiation antigen (CD) designations. Finally, some receptors have been named based on their function (e.g., the vitronectin, fibrinogen, and fibronectin receptors). Although functional designations are appropriate from a descriptive standpoint, at least two membrane proteins on platelets serve as receptors for vitronectin, fibrinogen, and fibronectin (see Table 127-2), and several platelet constituents have been referred to as collagen receptors (see later discussion). With the exception of the CD identifications, these latter nomenclature systems are rarely used compared with the GP and the integrin nomenclature, but they may be encountered in the older platelet literature. Beyond creating a nomenclature complexity, redundancy of platelet receptors endows the cell with the capacity to form multiple contacts with a single matrix constituent; thus, a single ligand may initiate several distinct functional responses by engaging different receptors.

The Integrin Family of Adhesion Receptors

Many of the adhesive protein receptors on platelets are members of the integrin family. It is estimated that half of the surface area of an activated platelet is occupied by integrins. The integrins are a broadly distributed family of heterodimeric (two subunits) cell surface molecules that share certain structural, immunochemical, and functional properties.[27-35] The ß subunits, of which eight are highly homologous, exhibit at least 35% to 45% identity at the primary amino acid sequence level and store a common structural organization. The α subunits, of which 18 are known, are also similar to one another but exhibit less extensive sequence homology.[36,37]

The α subunits fall into two categories, those with and those without I (A) domains. Integrin I domains are inserted domains of about 200 amino acids and are frequently involved in ligand binding of those integrins containing them.[38] As it turns out, only one of the major integrins on platelets, α2β1, a collagen receptor, contains an I domain in its α subunit. The α subunits are synthesized as single-chain polypeptides; some, such as αIIb, are proteolytically processed to a two-chain form.[39-42] Each β subunit forms a noncovalent complex with an α subunit to form a functional adhesive protein receptor. A single β subunit can combine with several α subunits.

Platelets express two major β subunits, β_1 and β_3 (low levels of β_2 have been reported, but this finding requires confirmation),[43] and five α-subunits (Table 127-3). Of the integrins expressed on blood cells, $\alpha_{IIb}\beta_3$ is the most narrowly distributed and is restricted predominantly to platelets and megakaryocytes. $\alpha_{IIb}\beta_3$ plays a prominent role in platelet aggregation and many other platelet responses, including the association of platelets with tumor cells, an interaction important for metastasis.[44-46]

Role of Glycoprotein Ib-V-IX in Platelet Adhesion

GPIb-V-IX is a notable example of a cell surface molecule involved in platelet adhesion that is not a member of the integrin family.[47] Platelets from patients with Bernard-Soulier syndrome lack GPIb-V-IX; these patients have a marked bleeding diathesis[48-50] (see Chapter 132). A major role of GPIb-V-IX in hemostasis can be traced directly to its function as a receptor for vWF. vWF is composed of multiple functional domains, including the 24kDa A1 domain that binds the amino-terminus of GPIbα and interacts, along with the A3 domain, with matrix constituents, such as collagen and microfibrils[18,51-57] (see Chapter 140). Thus, by associating with matrix proteins, vWF directly mediates rapid and reversible platelet adhesion that promotes the rolling of these cells along the surface of injured vasculature.[58] This rolling may transiently bridge the cells to subendothelial matrix components until a more stable adhesive bond forms. Integrins are the most likely receptors responsible for the stable platelet-adhesive bond that permanently halts the rolling of the platelet. In vitro, vWF does not interact directly with platelet GPIb, although such interactions can be induced by ristocetin, an antibiotic, or botrocetin (a snake venom peptide). Altered forms of vWF, such as asialo-vWF (which lacks sialic acid residues) and bovine vWF, can directly interact with platelets.[59-61] High shear serves as the physiologic counterpart of ristocetin or botrocetin in humans by altering vWF conformation and enabling this high-affinity interaction.[62,63] Such high shear stress can be attained in the microcirculation or in stenotic arteries.

Several laboratories have reported the structures of the vWF A1 domain, as well as A1 domain mutants that interact with the GPIβα complex.[64-66] The globular vWF A1 domain interacts with the amino-terminus of GPIbβα. The vWF-binding region of GPIbα is composed of two ß-loops, which flank a backbone composed of eight leucine-rich repeats. This entire interaction depends on displacement of the termini of the vWF A1 domains, an event that likely occurs under shear conditions that exist at sites of vascular injury. The interaction is complex and is best described as a "flex bond."[67] One state of the bond is seen at low forces, and a second and more stable state of the bond develops only at higher forces, such as those in the arterial system. This specialized type of interaction likely explains why the high shear in arteries promotes platelet plug formation.

The role of GPIb in hemostasis is not restricted to vWF binding. GPIb also serves as a binding site for thrombin,[68,69] and this activity may play an important role in the generation of platelet microparticles and procoagulant activity.[70-73] GPIb also is a target for certain drug-induced platelet antibodies[74] and is a counterreceptor for αMβ2 (CD11b/18, Mac-1), a leukocyte integrin, an interaction that promotes the formation of platelet-leukocyte conjugates.[75] The entire primary structures of GPIb,[76,77] GPIX,[78] and GPV[79] were determined by cDNA cloning approaches in the 1980s. GPIb is composed of a heavy chain (α) and a light chain (β), and both span the platelet membrane. GPIbα, which associates with the cytoskeleton within the platelet,[48,80-82] is susceptible to proteolysis, and a large proteolytic fragment, glycocalicin, can be detected in the plasma of some patients with thrombocytopenic disorders.[83] GPIX is a small, single-chain polypeptide with a molecular weight of 20,000 Da. The contribution of GPIX to the function of GPIb-V-IX is uncertain. GPV, which also is deficient in Bernard-Soulier platelets, forms a loose association with GPIb-V-IX.[50,70,71] Platelets from mice deficient in GPV exhibit enhanced sensitivity to thrombin, which may reflect a role of GPV in controlling the thrombin binding function of GPIb.[84] An important consequence of GPIb-V-IX occupancy by vWF is the induction of intracellular signaling events that ultimately lead to activation of $\alpha_{IIb}\beta_3$ and subsequent platelet aggregation[48,85] (see later discussion). Such communication between adhesion receptors is a repeating theme for platelets as well as for other cells. Key events in the communication among platelet receptors may include changes in the phosphorylation of the cytoplasmic tails of GPIb-V-IX and their association with the signaling molecule 14.3.3.[86,87]

Table 127-3 Platelet Integrins

Integrin	Major Ligands
$\alpha_2\beta_1$ (GPIa-IIa, VLA-2)	Collagen
$\alpha_5\beta_1$ (GPIc-IIa, VLA-5)	Fibronectin
$\alpha_{IIb}\beta_3$ (GPIIb-IIIa)	Fibrinogen, fibronectin, vitronectin, von Willebrand factor, CD40L
$\alpha_v\beta_3$ (Vitronectin receptor)	Fibrinogen, fibronectin, vitronectin, von Willebrand factor, thrombospondin, osteopontin
$\alpha_6\beta1$ (GPIc-IIa region)	Laminin

GP, Glycoprotein; *VLA,* very late antigen.

Collagen Receptors

Subendothelial collagen has long been recognized as an important initiator of platelet responses, serving both as a substrate for platelet adhesion and as a potent platelet agonist. Three different receptors have been implicated in the platelet responses to collagen.[88] First is the GPIb-V-IX complex mentioned above. Second is α2β1 (also known as VLA-2, platelet GPIa-IIa), a member of the integrin family of adhesion receptors that primarily serves as an anchor by which platelets attach to collagen that is exposed after disruptions of the vascular endothelium.[89] A patient with an acquired deficiency of this integrin exhibited a mild bleeding diathesis.[90,91] In addition to binding collagen with high affinity, α2β1 also binds laminins, E-cadherins, matrix metalloproteins, C1q, echovirus, and rotavirus. The identification of a patient with a mild bleeding diathesis who had normal amounts of α2β1 but reduced platelet glycoprotein VI (GPVI) suggested that GPVI also serves as a collagen receptor,[92] at least under low shear conditions. Platelets from mice lacking GPVI on the surface of their platelets exhibit absence of collagen-induced platelet activation and a profound reduction in collagen adhesion.[93] Deficiency of platelet GPVI can be induced by inactivating the GPVI or

the FcRγ genes. The latter forms a complex with GPVI and is required for its surface expression.[91] In contrast, α2β1 serves primarily as an auxiliary receptor for platelet adhesion to collagen and only functions as an agonist receptor under unusual circumstances.[89]

Experiments using receptor-blocking antibodies heterologously expressed receptors, and genetically altered mice have elucidated the roles of each of these proteins.[89,93-96] Platelet adhesion to collagen is a multistep process (Fig. 127-2). Initially, platelets adhere to collagen-immobilized vWF via platelet GPIb-V-IX. Although this interaction is rapid, it is transient. Consequently, the interactions repeatedly form and break, thereby causing the platelet to slowly roll along the surface of vWF that is immobilized upon exposed collagen. Ultimately, GPVI interacts directly with collagen, a low-affinity interaction that is a potent stimulus for intracellular signaling pathways. As a result of this signaling cascade, α2β1 is induced to bind collagen with high affinity, thereby forming a stable interaction. Thus, the interaction of platelets with collagen is complex. Whether pharmacologic inhibition of either platelet collagen receptor is of therapeutic benefit is unknown.

CLEC2 Adhesion Receptor

As described earlier, adhesion of platelets to a tear in the vascular system involves the binding of platelet GPIb-V-IX and α2β1

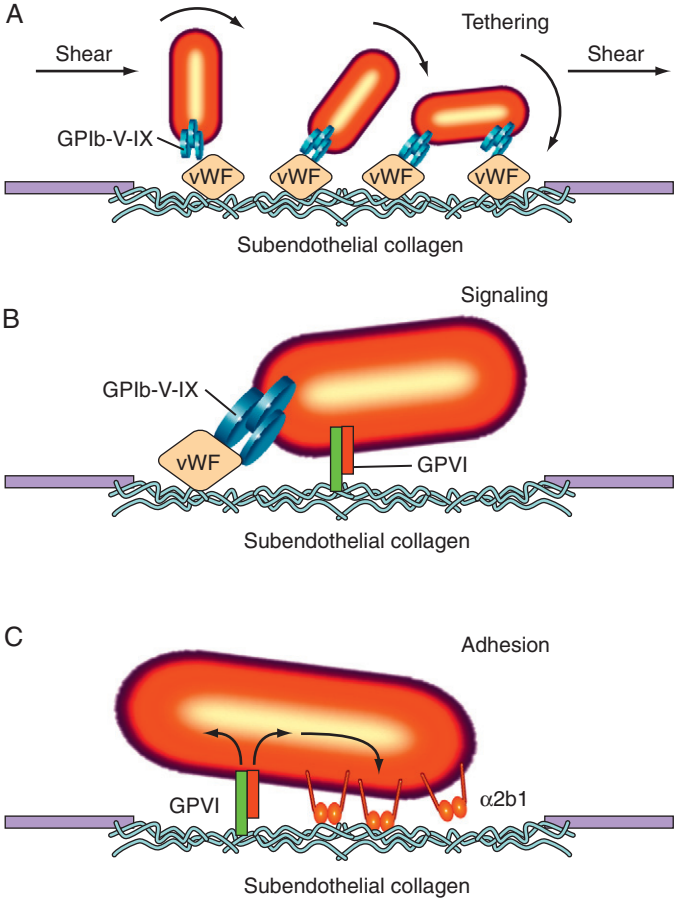

Figure 127-2 ADHESION TO COLLAGEN IS A MULTISTEP PROCESS. **A,** After being exposed to an injured vessel wall, von Willebrand factor (vWF) adheres to subendothelial collagen, where it undergoes a conformational change that allows it to bind to the platelet receptor glycoprotein (GP) Ib-V-IX. This rapidly formed bond is quickly broken and reestablished, causing the platelet to roll along the injured vessel wall. **B,** The rolling process slows platelet transit and allows the platelet signaling receptor, GPVI, to bind collagen. **C,** This induces a cascade of signaling events that ultimately activate the integrin, α2β1. The final association between the platelet and collagen is stable and allows the platelet to firmly adhere to the vessel wall.

receptors followed by intracellular signaling initiated by GPVI. CLEC2[97] is a recently identified type II transmembrane receptor with C type lectin-like extracellular domains encoded by genes within the genomic natural killer (NK) receptor complex. CLEC2 is highly and selectively expressed on platelets, although it is also found on neutrophils.[98,99] Initially described as the receptor responsible for platelet activation by the snake venom rhodocytin, CLEC2 was later identified as the receptor responsible for platelet activation by the transmembrane glycoprotein podoplanin.[99] Activation of CLEC2 by podoplanin induces a series of platelet signaling events similar to those induced by collagen after it binds to the GPVI receptor. Recent work has demonstrated that infusion of antibodies against CLEC2 into mice affords them with significant protection against occlusive thrombus formation.[100] Rational drug design approaches could exploit this knowledge to develop specific CLEC2 inhibitors.

Reorganization of the Actin Cytoskeleton

One of the more dramatic events during platelet activation is the metamorphosis that occurs when platelets adhere and spread on exposed collagen fibrils or become activated in the circulation by soluble factors such as thrombin or ADP. In both cases, platelets lose their distinct discoid shape and acquire an irregular morphology with multiple filopodial projections.[101] This transformation is associated with and largely attributable to cytoskeletal rearrangements within the platelet.[102] The proteins are arranged in three major structures: a cytoplasmic actin network, a rim of membrane-associated cytoskeleton, and a marginal band consisting of a microtubule coil.[103] Together these structures lend support to the platelet plasma membrane and give shape to both resting and activated platelets. The capacity to rapidly reorganize these structures allows the platelet to firmly adhere to breaks in the blood vessel wall under conditions of shear found within the arterial vascular system.

The cytoplasmic actin network is composed of actin filaments and associated proteins. Actin is a 42-kDa protein that accounts for as much as 20% of total platelet protein.[103] In resting platelets, 40% to 50% of the actin is filamentous F-actin, and the remainder is globular monomeric G-actin.[104,105] The shift that increases the proportion of F-actin to 70% to 80% during platelet activation involves a coordinated sequence of events in which the actin filaments in resting platelets are severed and the resultant smaller fragments are used as the nidus for new, longer actin filaments. This process is regulated in part by the increase in the levels of a phosphoinositide (phosphatidylinositol 4,5 bisphosphate [PIP2]) that accompanies platelet activation.[106-109] At the same time, myosin is phosphorylated by myosin light chain kinase and becomes associated with F-actin, thereby forming filaments that are anchored to the platelet plasma membrane by attachment (via actin-binding protein) to the GP Ib-V-IX complex.[110,111]

The cytoskeletal rim is composed of actin, filamin, P235 (talin), vinculin, spectrin, α-actinin, and several membrane glycoproteins. Filamin is an elongated 280-kDa protein that is present in platelets and functions as an actin binding protein.[112] In resting platelets, filamin is part of a semirigid array that helps to maintain the platelet's discoid shape and limits the lateral movement of GPIb.[80,113,114] This role is analogous to that performed by spectrin in erythrocytes.[81] When platelets are activated, actin filaments form and attach to actin-binding protein. Later, the rising cytosolic Ca^{2+} concentration activates calpain, which cleaves actin-binding protein, severing the link to GPIb.[113,115,116] Recent evidence in genetically engineered mice has also demonstrated that the synthesis of PIP2 is critical for stable adhesion of the actin cytoskeleton to the cell membrane.[109] Available data suggest that this anchoring of the cell membrane to the underlying cytosketelon is mediated, at least in part, by talin (as discussed in the section Activation of $\alpha_{IIb}\beta_3$).

The third major structural element in platelets is the marginal microtubule band.[103] This microtubule coil is a single tightly wound polymer of tubulin that encircles the platelet perimeter and helps to maintain its discoid shape.[117] During platelet activation, the

microtubule coil contracts. Although it has been proposed that contraction of the marginal band is required for stable adhesion of platelets under arterial shear pressures, this concept remains controversial.[118,119]

PLATELET SECRETION

The foregoing discussion has emphasized the adhesive functions of platelets in mediating the physical closure of breaks in blood vessels. Another important function of platelets is the release of a variety of substances that stimulate or inhibit platelets or other blood and vascular cells, covalently modify the thrombus to affect its mechanical properties, regulate coagulation, contribute to cell adhesive events, and modulate the growth of cells of the vessel wall. Thus, the platelet is not simply the stop plug of the vasculature but also has the capacity to signal its presence in a thrombus and modify the hemostatic response. In addition, although platelets are anucleate, they contain mRNA and can synthesize some proteins.[120,121] Although such synthesis had long been regarded as a vestigial activity of megakaryocytes, recent data indicate that platelets synthesize a restricted repertoire of proteins that are related to apoptosis and inflammation,[122] the so-called platelet "transcriptome."[121] Most of the substances that are actively and selectively secreted from platelets are packaged in preformed storage granules or are synthesized de novo from membrane phospholipids. Platelets contain three types of granules: (1) dense granules that contain platelet agonists that serve to amplify platelet activation, (2) α granules that contain proteins that enhance the adhesive process, and (3) lysosomal granules that contain glycosidases and proteases that have an unclear function in platelet biology.[123] In addition, factors in the platelet cytoplasm can have effects on thrombus structure or on vascular cell growth; they are released as a result of minor degrees of platelet lysis during hemostasis. Some of these factors and their intraplatelet sources are illustrated in Fig. 127-3, *A*.

Dense Granules

The dense bodies and platelet membranes are a source of rapidly secreted mediators. These mediators are either quickly inactivated or promptly diffuse away from the site of the thrombus, so they function for only a brief period of time. Their rapid effects on surrounding cells serve to modulate the behavior of platelets, as well as the behavior of vessel wall cells (particularly with regards vascular tone).

Platelets contain approximately three to eight dense granules, which are the most rapidly secreted platelet organelles.[124] These granules contain and upon activation release ADP (which is a potent agonist that recruits other platelets) as well as adenosine triphosphate (which is an agonist for other cells of the blood).[125,126] Additionally, they release biogenic amines such as serotonin, which can influence vascular tone, and divalent cations. The physiologic role of released dense body calcium is not clear; however, it may serve to ensure that there is sufficient calcium for the calcium-dependent enzymes involved in coagulation or cross-linking of fibrin.

α Granules

A large number of plasma proteins involved in cell adhesion and coagulation are also present in platelet α granules. Some of the

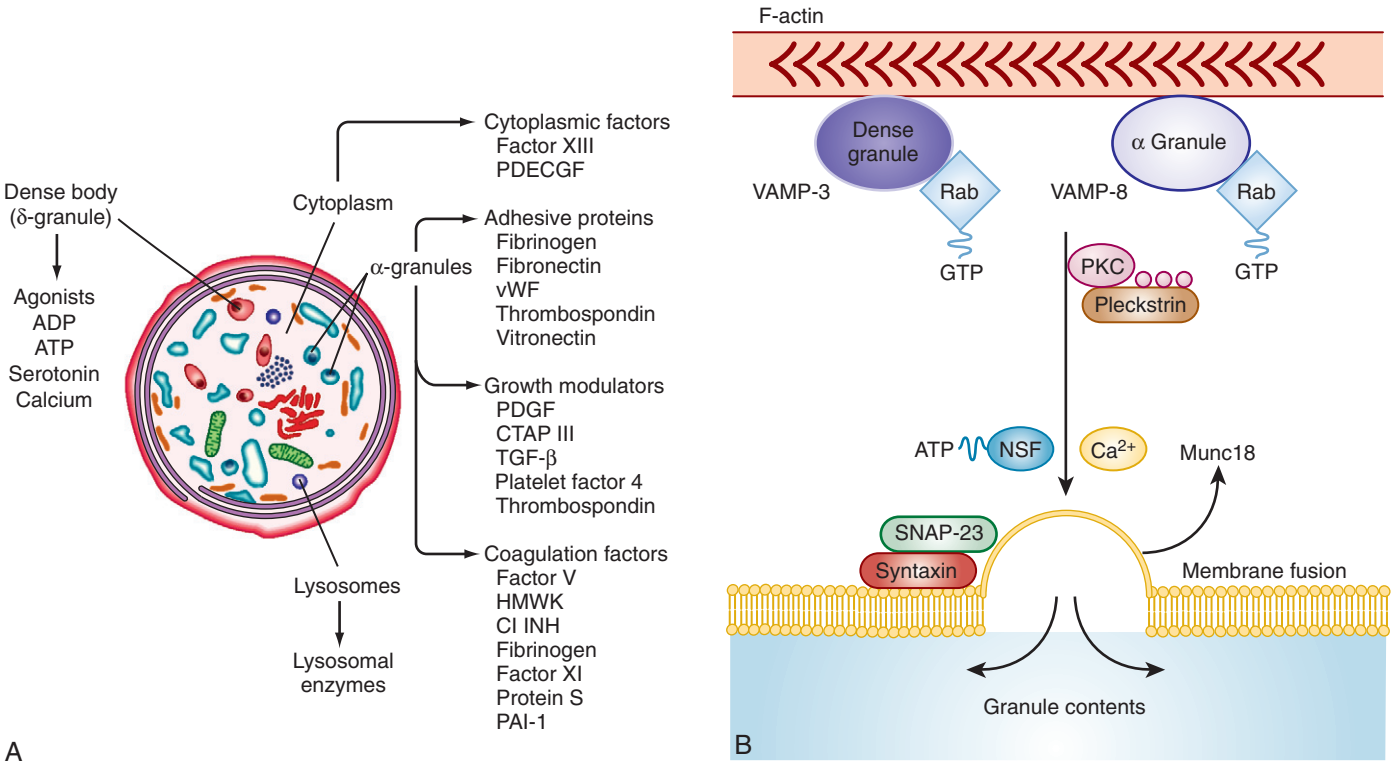

Figure 127-3 A, SUBSTANCES RELEASED BY PLATELETS AND THEIR INTRAPLATELET SOURCES. Illustrated are some of the bioactive substances released from dense bodies, α granules, lysosomes, the cytoplasm, and the platelet membrane. *C1 INH,* C1 inhibitor; *CTAP,* connective tissue activating peptide; *HETE,* hydroxyeicosatetraenoic acid; *HMWK,* high-molecular-weight kininogen; *PAF,* platelet-activating factor; *PAI-1,* plasminogen activator inhibitor-1; *PDECGF,* platelet-derived endothelial cell growth factor; *PDGF,* platelet-derived growth factor; *TGF-B,* transforming growth factor-b; *vWF,* von Willebrand factor. **B,** In resting platelets, the actin cytoskeleton needs to be disassembled before platelet secretion. Secretion of α and dense granules occurs through a complex signaling pathway dependent on small GTPases, protein kinases, phosphorylated pleckstrin, and members of the SNARE (soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor)/SNAP (soluble NSF attachment protein) family. These signaling pathways are highly homologous to those used during neuronal cell exocytosis. *ATP,* Adenosine triphosphate; *GTP,* guanosine-5'-triphosphate; *NSF,* N-ethylmaleimide-sensitive fusion; *PKC,* protein kinase C; *VAMP-8,* vesicle-associated membrane protein 8.

proteins found within α granules are only synthesized in megakaryocytes (e.g., β thromboglobulin and platelet factor 4), but others are less specific for platelets and megakaryocytes. Platelets contain approximately 80 α granules that contain adhesive plasma proteins including vWF, fibrinogen, fibronectin, and vitronectin, as well as the platelet and cellular adhesive protein thrombospondin-1.[22,127] Platelet vWF is concentrated in the platelets; megakaryocytes synthesize it[128]; and the platelet form is enriched in the larger, presumably more hemostatically effective multimers.[129] Megakaryocytes clearly take up fibrinogen, but its biosynthesis in megakaryocytes remains controversial.[130] Platelet fibronectin appears to be enriched in alternatively spliced forms that are relatively lacking in plasma,[23] suggesting a possible role for platelet fibronectin in events such as matrix assembly. Vitronectin is present in platelets[131]; however, its concentration suggests that it is passively taken up from plasma. Nevertheless, recent studies have suggested a role for platelet and plasma vitronectin in thrombus formation.[132,133] Plasminogen activator inhibitor type 1 (PAI-1) binds vitronectin,[134] and these two proteins are released in complex.[135] Consistent with this observation, mice lacking vitronectin, PAI-1, or both proteins have a similar deficiency in thrombus formation.[136] A wide variety of procoagulant and anticoagulant enzymes and cofactors have been reported in platelet granules. Although controversial,[137] it appears that megakaryocytes synthesize factor V,[138-140] and more factor V is found in platelet α granules[141] than can be accounted for by nonspecific uptake from plasma. Moreover, platelet factor V is distinct from plasma factor V[142] and plays an important role in platelet prothrombinase assembly.[143] Platelets also contain protein S[144] and PAI-1.[145] Protein S is a cofactor for activated protein C (see Chapter 129), and PAI-1 is an inhibitor of urokinase and tissue plasminogen activators (see Chapter 129). The concentration of these proteins in platelets suggests that platelets may be a favored site for the anticoagulant action of activated protein C, a tempting idea considering the high concentration of factor Va, its substrate, on the platelet surface. Similarly, the local release of PAI-1 from platelets may play a role in modulating the fibrinolytic events in the vicinity of thrombi.[146,147] P-selectin[148-151] (also known as GMP-140, GPIIa, PADGEM, and CD62) is an α-granule membrane protein that is absent from the surface of resting platelets. It is structurally similar to E- and L-selectin,[152] a family of carbohydrate-binding proteins involved in adhesive interactions of circulating leukocytes. Platelet P-selectin plays a central role in mediating interactions of monocytes and neutrophils with platelets.[152] These interactions are important for "cross-talk" between these cell types[153] and for the recruitment of leukocytes to thrombi.[154] Some of the proposed pathogenetic roles of platelet P-selectin include promoting thrombogenesis,[154] platelet–tumor cell interactions,[155] and monocyte recruitment. It may also play a physiologic role in leukocyte phagocytosis of platelets. In addition, P-selectin plays a role in leukocyte–vessel wall interactions[151,156] and hemostasis.[157] Increased numbers of platelet–leukocyte conjugates are found in the plasma of patients with acute coronary events; a finding consistent with platelet activation.[158,159] However, P-selectin and its counterreceptor, PSGL-1 (P-selectin glycoprotein ligand-1), on leukocytes[160] are not the only ligand–receptor pair that mediates these interactions.[161]

The most abundant component of α granules is platelet activating factor[162] (alkyl-2-acetyl-*sn*-glycero-3-phosphocholine), which was originally described as a platelet activator released from stimulated mast cells. It is a member of the chemokine family, and its biologic effects extend beyond platelet activation.[163-165] Platelet activating factor plays a role in the platelet sequestration that occurs with allergic injury, but it is produced by other cells as well as platelets. Is it possible that local generation of this mediator contributes to platelet recruitment or to some of the vascular phenomena associated with hemostasis.

Platelet α granules contain Gas6 (growth-arrest specific gene 6), a vitamin K–dependent protein with homology[166,167] to protein S that serves as a ligand for growth factor receptors, such as Axl.[168] Because platelet express the Axl receptor, it is speculated that secreted Gas6 functions to accelerate platelet recruitment and activation. Consistent with this concept, mice lacking Gas6 have a platelet defect.[142,166]

Platelets are the major peripheral blood source of β-amyloid precursor protein (APP).[169] APP is a membrane protein, thought to be localized to α granules,[170] that serves as the precursor of the approximately 40 residue peptides found in amyloid deposits in the brains of patients with Alzheimer disease. APP is a protease inhibitor and is processed by proteolytic cleavage. Its capacity to inhibit factors Xa, XIa, and IXa[171,172] suggests that it may function as a natural anticoagulant. Platelets contain a wide variety of peptides and proteins, primarily in α granules, that can modulate the growth and patterns of gene expression of cells of the vessel wall. The first of these to be described was platelet-derived growth factor[173] (PDGF), which has three isoforms and two distinct receptors on smooth muscle cells and fibroblasts.[174] PDGF probably plays an important role in the smooth muscle cell proliferation that may occur after platelet interaction with the vessel wall. In fact, platelet-secreted PDGF may play a critical role in angiogenesis.[175] The PDGF receptors are transmembrane tyrosine kinase–type receptors, and signal transduction from these receptors[176] is similar to that from other tyrosine kinase receptors, such as the insulin and epidermal growth factor receptors. Another α-granule growth factor is connective tissue activating peptide (CTAP) III, which stimulates fibroblast proliferation. CTAP III is the likely precursor of β thromboglobulin,[177] and its structure is related to another α-granule protein, platelet factor 4. Both platelet factor 4 and CTAP III are members of a large protein family involved in growth control and inflammation.[178] Although interleukin-1 is expressed on the surface of activated platelets,[179] its origin is unclear.

Transforming growth factor (TGF)-β was first isolated from platelets,[180] and platelets are a rich source of this peptide mediator, which is a potent stimulus for the biosynthesis of matrix molecules and their receptors. TGF-β has complex effects on cell proliferation, stimulating some cells and inhibiting others. In addition, thrombospondin-1 is present in and secreted from platelet α granules. Released thrombospondin-1 is believed to play a role in stabilizing platelet aggregates via its interaction with platelet cell-surface receptors and fibrinogen bound to integrin αIIbβ3.[181] An additional important role of thrombospondin-1 is its function as an activator of TGF-β[182] and as a potent antiangiogenic factor.[183] This latter function may explain how platelets contribute to the regulation of angiogenesis.[184]

Thrombospondin-1 also is produced by endothelial and smooth muscle cells, and its mRNA is inducible by growth factors such as PDGF.[185,186] Indeed, thrombospondin-1 appears to play a role in the regulation of smooth muscle cell proliferation and angiogenesis.[187-189] Platelets also contain and secrete vascular endothelial cell growth factor (VEGF).[190] Recent data suggest that platelets contain subpopulations of α granules that differ in their VEGF content. Thus, some platelet α granules may be enriched in their content of proangiogeneic factors, but others contain mainly antiantiogeneic factors.[191] Also, it has long been known that platelets and megakaryocytes can take up proteins into their α-granules,[192] and it has recently been suggested that their content can reflect microenvironmental changes, such as the presence of tumors.[193] Many clinical studies have assessed the prognostic or diagnostic value of markers, including VEGF, in a variety of diseases, raising the possibility that the platelet protocol may be useful to identify or monitor certain illnesses.

Multimerin is a novel platelet and endothelial protein that exists as massive disulfide-linked multimers composed of a 155-kd subunit.[194,195] Multimerin has a repeating structure, and its sequence contains the adhesive Arg-Gly-Asp-Ser motif, central coiled-coil sequences, several epidermal growth factor-like motifs, and a globular domain that is similar to the protein binding domain found in complement C1q and type VIII and X collagens.[196] Multimerin binds the coagulation protein factor V and its activated form, factor Va. In platelets but not in plasma, all of the biologically active factor V is complexed with multimerin.[197] Multimerin may also have functions as an extracellular matrix or adhesive protein. This large granule protein may play important roles in platelet procoagulant activity and in platelet adhesion.

Lysosomal Granules and The Platelet Cytosol

Platelets contain a few primary and secondary lysosomes[33,123] whose enzymes are released, but platelets are probably a minor source of lysosomal hydrolases in the blood compared with neutrophils. Nevertheless, mention should be made of platelet-associated heparatinase,[198] which can cleave vascular endothelial cell surface glycosaminoglycans to produce an antiproliferative fragment.

Factor XIII, a transglutaminase that catalyzes the formation of isopeptide bonds between the γ-glutaminyl residues and the E amino groups of lysines, forming stable covalent cross-links between proteins, is contained in the platelet cytosol.[199] It is likely that small quantities of platelet factor XIIIα are released into thrombi and serves to cross-link fibrin and to cross-linking fibronectin[200] and α_2-antiplasmin[201] onto fibrin (see Chapter 129). Platelet factor XIII may also play a role in cross-linking and stabilizing cytoskeletal elements.[202,203] Also, transglutaminases have been implicated in the signaling events associated with occupancy of G protein–coupled receptors,[204,205] and many of the agonist receptors, which activate platelets, are members of this family.

Secretion

The secretion of platelet granules occurs through mechanisms analogous to those required for the exocytosis of granules from neurons and mast cells. Platelet secretion is triggered by a variety of strong agonists such as thrombin. Induction of secretion by weak agonists (e.g., ADP) occurs when the cells are brought into close contact, such as occurs during aggregation.[123,206,207] The latter secretory mechanism is clearly dependent on thromboxane A_2 (TXA_2) generated as a consequence of arachidonic acid release.

Granule Exocytosis

As noted previously, the two morphologically prominent platelet storage granules, α granules and dense bodies, contain a variety of substances important in platelet function. Because these granules have a limiting membrane, it is likely that the final secretory event involves exocytosis[208] (i.e., fusion of the secretory granule membrane with the plasma membrane). This has been observed in dense body secretion.[209,210]

Identification of the role of the soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) complex in neuronal cell exocytosis has advanced our understanding of platelet secretion. Platelets have the three basic components of SNARE machinery: t-SNAREs (target receptors), v-SNAREs (vesicle-associated membrane receptors), and soluble components (including NSF and NSF-attachment proteins).[123,207] Through a pathway involving Rab-GTPase, protein kinase C (PKC), and intracellular calcium, the SNARE machinery regulates the association and subsequent fusion of vesicles with membranes (see Fig. 127-3, *B*). Mice deficient in one of these SNAREs, VAMP-8 (vesicle-associated membrane protein 8), exhibits defective platelet secretion,[211,212] and certain single nucleotide polymorphisms in VAMP-8 have been associated with increased susceptibility to acute myocardial infaction.[213] Recent evidence has demonstrated that pleckstrin, a substrate of PKC, is a critical mediator of this process.[214] In mouse platelets lacking pleckstrin, secretion in response to PKC-dependent signaling pathways is lacking because of a failure of the membranes of the granules to fuse with the cellular membrane.

Mention should also be made of platelet microparticles. These vesicles are shed from the membrane of stimulated platelets. In addition to membrane lipids, they are enriched in certain platelet membrane proteins,[215] which enables their detection by flow cytometry.[216] Microparticles are highly procoagulant, and they may contribute to the thrombotic complications associated with heparin-induced thrombocytopenia (see Chapter 135),[217] and their presence in blood has been correlated with coronary artery disease.[218-221]

In addition to the outward movement of granules toward the cell surface, it is clear that there is also substantial inward membrane traffic in platelets.[222-225] This inward traffic serves to clear adhesive and procoagulant proteins from the cell surface and hence limit prothrombotic events.[226]

Eicosanoids and Arachidonate

In addition to exocytosis of platelet granules, the passive release of TXA_2 from platelets is another mechanism by which platelet activation is amplified. Eicosanoids are formed from the arachidonate released from membrane phospholipids by phospholipase A2 during platelet activation.[227-229] Because the availability of arachidonate is the rate-limiting step in this process, phospholipase A2 is tightly controlled. Platelet phospholipase A2 is stimulated by the rise in the cytosolic Ca^{2+} that accompanies platelet activation.

After being released from membrane phospholipids, arachidonate can be metabolized to TXA_2by cyclooxygenase-1 (COX-1).[230] Aspirin acetylates COX-1, causing it to be irreversibly inactivated.[231] Because platelets lack the ability to synthesize significant amounts of protein, inactivation of COX-1 by aspirin blocks TXA_2synthesis until new platelets are formed. However, there may be a subset of patients who are "aspirin resistant," although the molecular basis of this disorder and a universally accepted definition are elusive.[232,233] Aspirin resistance can lead to undermedication of patients and therefore an increased risk for recurrent thrombotic events. Nonsteroidal antiinflammatory drugs also inactivate COX-1 but without covalently modifying the enzyme.[234]

After forming, TXA_2 can diffuse across the plasma membrane and activates other platelets through signaling pathways. This leads to platelet shape change, aggregation, secretion, phosphoinositide hydrolysis, protein phosphorylation, and an increase in cytosolic Ca^{2+} while having little effect on cyclic AMP formation (see Chapter 132).[235] Similar to ADP, TXA_2 amplifies the initial stimulus for platelet activation and recruits additional platelets. This process is effective locally but is limited by the short half-life of TXA_2, which confines the spread of platelet activation to the vicinity of the injury.

MOLECULAR BASIS OF PLATELET AGGREGATION

Aggregation Response of Platelets

Platelets in blood, in plasma, or as an isolated cell population do not interact with one another. If an appropriate agonist is added, rapid platelet aggregation ensues. Some of the agonists that initiate this response are listed in Table 127-4. Of particular physiologic relevance

Table 127-4 Common Platelet Aggregating Agonists

Agonist	Comment
Adenosine diphosphate (ADP)	Released from platelet α granule; acts synergistically with many other agonists
Thrombin	Formed by activation of the coagulation system
Collagen	In subendothelial matrix
Epinephrine	May allow for hormonal regulation of hemostasis
Calcium ionophore	Not naturally occurring; mobilizes calcium in platelets
Arachidonate and its metabolites	Active metabolites are formed and released from stimulated platelets
Serotonin	Released from platelets; may primarily sensitize platelets to other agonists
Platelet-activating factor	Lipid mediator produced by other cells that can activate a variety of cells, including platelets

are the platelet-derived agonists—ADP, serotonin, platelet activating factor, and arachidonate metabolites—that provide a means for stimulated platelets to recruit additional cells; collagen, which supports platelet adhesion and secretion as well as aggregation; thrombin, which links platelets and the blood coagulation system in thrombus formation; epinephrine, which permits hormonal regulation of platelet function; and vWF upon its binding to GPIb-V-IX. These agonists activate platelets by interacting with specific receptors, many being members of the G protein–coupled receptor class. Receptor occupancy triggers a complex series of intracellular reactions (detailed in Chapter 132) that ultimately converge to a set of common steps that permit the cells to aggregate. Platelet aggregation is energy dependent and can be distinguished on this basis from platelet agglutination induced by ristocetin or certain platelet antibodies.

At normal blood concentrations of 1 to 3 × 10^8/mL, platelet suspensions are opalescent. On addition of an agonist, a stirred suspension of normal platelets aggregates and a decrease in turbidity is observed. Platelet aggregometers, which monitor the change in light transmission through platelet suspensions, are used extensively in clinical laboratories to evaluate platelet function (see Chapter 131). Certain instruments also provide simultaneous measurements of other platelet functions, such as secretion.[206] Although the information gained from aggregometry can be extremely useful, aggregation in vitro does not necessarily reflect platelet function in vivo. In particular, clinical bleeding and the aggregation response of platelets do not necessarily coincide. This disparity reflects the importance of platelet adhesion in thrombus formation, a reaction that is not detected by aggregometry. For this reason, instruments that measure platelet adhesion under shear or provide more quantitative information are sometimes used to monitor antiplatelet therapy.[236-238] Nonetheless, aggregometry remains the mainstay of the clinical coagulation laboratory.

A typical aggregometer tracing obtained with a suspension of isolated human platelets is shown in Fig. 127-4, *A*. From this pattern, the three essential components required for this functional response can be identified. The first component is the *platelet agonist.* The agonist used in Fig. 127-4 is ADP. This agonist induces platelet shape change from discoid to a more spherical form, a transition that can be detected in the aggregometer as a decrease in light transmission. This transformation is not a prerequisite for platelet aggregation; epinephrine aggregates platelets but does not induce a shape change that is recordable by conventional aggregometers. At the molecular level, shape change reflects a reorganization of the actin cytoskeleton. The second component is *divalent cations.* Calcium and magnesium, as well as other (but not all) divalent cations, support platelet aggregation.[239-241] The third component is *fibrinogen.* Fibrinogen is not only a major plasma protein but is also present in and secreted from platelets[242,243] (see Chapter 118). By virtue of its capacity to form fibrin and support platelet aggregation, fibrinogen plays a dual role in thrombus formation. These activities, as well as the contribution of fibrinogen to blood viscosity, are believed to account for the increased risk of cardiovascular disease associated with elevated levels of fibrinogen.[244-246] In addition, certain single nucleotide polymorphisms in fibrinogen also have been associated with an increased risk of cardiovascular stroke in some but not all studies.[247-249] The dependence of platelet aggregation on fibrinogen concentration is evident from the tracings illustrated in Fig. 127-4, *B*.

Although not evident by conventional aggregometry, vWF plays a central role in platelet aggregation and in the more complex process of thrombus formation, which entails platelet adhesion as well as aggregation. The role of vWF in platelet aggregation becomes apparent in certain pathologic circumstances such as platelet-type von Willebrand disease and type IIB von Willebrand disease (see Chapter 140).[250-254] In the setting of vascular injury in vivo, it is clear that both molecules, fibrinogen and vWF,[1-3] as well as other identified and as yet unidentified plasma and platelet molecules[4,255] contribute to thrombus formation and stability.

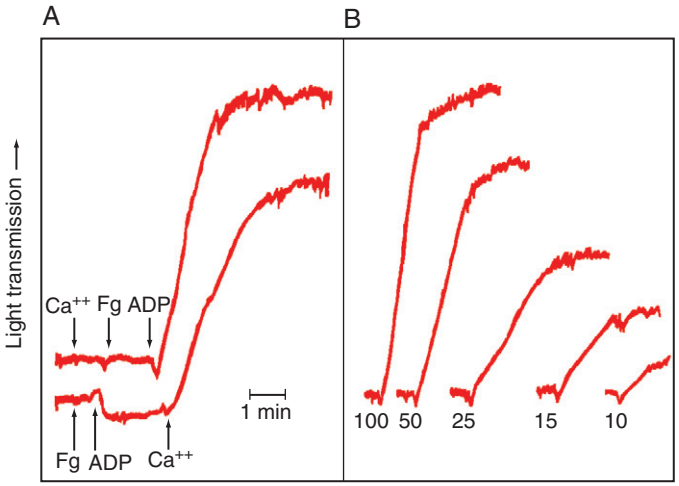

Figure 127-4 AGGREGATION RESPONSE OF HUMAN PLATELETS. **A,** To aggregate, isolated human platelets require divalent ions (Ca^{2+}), an agonist (adenosine diphosphate [ADP]), and an adhesive protein (fibrinogen [Fg]). Shape change is observed as a slight decrease in light transmission induced by ADP and is followed by an increase in transmission as the platelets aggregate. **B,** Both the rate and extent of platelet aggregation depend on the concentration of fibrinogen. The concentration of fibrinogen (in μg/mL) is indicated below each tracing.

Molecular Mechanisms Involved in Platelet Aggregation

The basis for the requisite roles of the agonist, calcium, and fibrinogen and vWF in platelet aggregation is now well understood at a molecular level. Fibrinogen and vWF are ligands for integrin αIIbβ3. Absence or dysfunction of this integrin on the surface of platelets leads to Glanzmann thrombasthenia, a condition characterized by absent platelet aggregation. Further evidence for the critical role of αIIbβ3 in platelet aggregation and thrombus formation comes from genetically modified mice that are unable to express this receptor. These mice are unable to form a thrombus.[256] In contrast, mice that lack ligands for this receptor can still form a thrombus,[1-4] although increased bleeding may be observed. An agonist is necessary to convert αIIbβ3 from its resting state on circulating platelets in which the integrin is unable to bind its plasma protein ligands to an activated state in which ligands bind rapidly. All of the platelet agonists listed in Table 127-4 can initiate platelet aggregation through this pathway. Calcium is needed for fibrinogen and vWF binding to activated αIIbβ3. Activation of αIIbβ3 by agonists is very rapid; the receptors become fully competent to bind fibrinogen or vWF seconds after platelets encounter an appropriate agonist. More than 40,000 fibrinogen molecules can be bound to the platelet surface via αIIbβ3.[239,257-259] Fibrinogen is a dimer and vWF a multimer. By virtue of their repeating and large structures, these ligands can bind to αIIbβ3 on adjacent platelets and bridge the cells together, leading to formation of platelet aggregates.[241,260-263]

$\alpha_{IIb}\beta_3$: Structure–Function Relationships

The resting platelet has 40,000 to 80,000 copies of $\alpha_{IIb}\beta_3$ on its surface,[264] and platelet activation can produce a further 10% increase in this number as a result of expression of internal receptor pools.[265] Each $\alpha_{IIb}\beta_3$ is capable of binding one fibrinogen molecule. $\alpha_{IIb}\beta_3$ is a typical integrin composed of an α and a β subunit, which combine to form a heterodimer.[34,36] The α subunit, α_{IIb} (GPIIb), is expressed primarily by cells of the platelet/megakaryocyte , although expression by various solid tumors and mast cells has also been reported.[266-268] The β_3 subunit, GPIIIa, forms a complex not only with α_{IIb} but also with the α_V subunit to form $\alpha_v\beta_3$.[269] $\alpha_v\beta_3$ is expressed by a variety of

cell types, including platelets, megakaryocytes, and endothelial cells.[270-272] These two sister receptors bind many of the same ligands and antagonists, but their specificities are not identical.[273] Complete amino acid sequences of both α_{IIb} and β_3 subunits were deduced from their cDNAs sequences.[37,40] The carbohydrate side chains and disulfide linkages were also located.[274-277] α_{IIb} is synthesized in megakaryocytes as a single chain but becomes proteolytically processed to the two-chain form during its transit to the cell surface.[278]

Structural biology studies have provided significant insights into the molecular basis for the functions of $\alpha_{IIb}\beta_3$ and $\alpha_V\beta_3$. The crystal structure of the extracellular domain of $\alpha_V\beta_3$ was solved with and without a bound peptide ligand (see later discussion).[279,280] A schematic model illustrating the domain organization derived from these crystal structures is shown in Fig. 127-5. The extracellular domain of each subunit is composed of several domains, and at least one domain from each subunit directly contacts bound ligand. The primary ligand contact domain in the α subunit is termed the β-propeller domain. It is composed of seven "blades" and homologous structures are found in G proteins. In the β subunit, an A domain, also referred to as an I domain, contacts ligand. The β propeller and A domain come into close proximity to form a globular head that is apparent in electron micrographs of isolated $\alpha_{IIb}\beta_3$.[281] Within the A domain of the β_3 subunit are three divalent cation binding sites, and one of these, termed the metal ion-dependent adhesion site (MIDAS), is intimately involved in ligand binding. One of the coordination sites for the cation bound within the MIDAS can be provided by an aspartic acid within the ligand. Thus, occupancy of the MIDAS cation establishes the role for divalent ions in ligand binding and platelet aggregation (see Fig. 127-5). Located within the α_{IIb} and β_3 stalks, which extend out from the globular head, is a "genu," which allows bending so that the head domain can approach the cell membrane. It was this bent structure that was observed in the $\alpha_V\beta_3$ crystal structures. Subsequently, several crystal structures of portions of the extracellular domain of αIIbβ3 also were solved.[282] Structures with antagonists bound to the receptor illustrate how low molecular weight ligands bind to $\alpha_{IIb}\beta_3$.

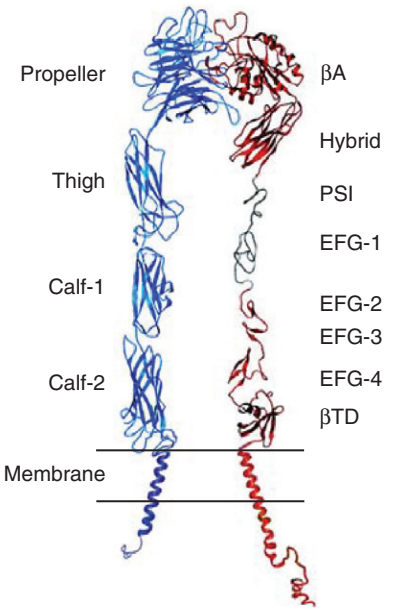

Figure 127-5 MODEL SHOWING THE STRUCTURAL ORGANIZATION OF A β3 INTEGRIN. The model is based on the crystal structure of the extracellular domain of $\alpha_V\beta_3$ and the cytoplasmic tails on the nuclear magnetic resonance (NMR) structure of $\alpha_{IIb}\beta_3$. *(Adapted from Xiong JP, Stehle T, Goodman SL, et al: Integrins, cations and ligands: Making the connection. J Thromb Haemost 1:1642, 2003 and Qin J, Vinogradova O, Plow EF: Integrin bidirectional signaling: A molecular view.* PLoS Biol *2:e169, 2004.)*

Structures for the transmembrane domains and the cytoplasmic tails also are available.[283-287] The transmembrane segment of each subunit is composed of an α helix,[287-289] and these transmembrane helices interact with each other.[290] Two recent structures of the transmembrane helices are similar but differ in the region where α_{IIb} enters the cytosol, one showing an inverse turn[288] and the other indicating a helical region that extends into the cytosol.[289] This distinction is important because this segment is reported to be the binding site for several molecules that regulate integrin-mediated signaling and may or may not be available for such interactions. Regardless, it is clear that the regions proximal to the cytosolic membrane of both α_{IIb} and β_3 are helical, and these helices interact weakly with each other. The dissociation of this "CT membrane complex" is a key regulatory event in integrin activation.[284]

Activation of $\alpha_{IIb}\beta_3$

$\alpha_{IIb}\beta_3$ activation is initiated by a platelet agonist and involves transmission of a signal induced by engagement of the agonist receptor to the cytoplasmic tail of the integrins. The signal is then transmitted from the cytoplasmic tail through the transmembrane helices and ultimately induces a change in the extracellular domain to render the integrin functional. The signaling process responsible for this transformation is referred to as "inside-out" signaling.[291-293] Although a model depicting the structural basis of inside-out signaling has emerged, many specific details have yet to be resolved. An integrin activator binds to the cytoplasmic tail of $\alpha_{IIb}\beta_3$ and disrupts the complex between the subunits.[284,294,295] The dissociation triggers a conformational change that is transmitted into transmembrane segments and disturbs their interaction.[290] These events are then transmitted to the extracellular region, allowing for acquisition of ligand competence. Within the transmembrane region, disassembly of the intramolecular interactions between helices initiates homo-oligomerization between like subunits.[287,290,296] Consequently, the integrin heterodimers become clustered. Such clustering in itself can lead to or enhance activation by enhancing the avidity of the clustered extracellular domains for ligand or by altering the conformation of the extracellular domain.[297-299]

The crystal structures of the extracellular domain of $\alpha_V\beta_3$ revealed bent structures with the head domain in proximity to the cell membrane.[279] This configuration was unanticipated because most electron micrographs suggested that the head domain resided at the end of long, straight stalks.[281] These seemingly disparate results were reconciled by a "switchblade" hypothesis, which suggests that there is sufficient flexibility that the integrin can either assume a bent or an extended conformation. Detailed micrographic studies supported the notion that the integrin can transition between these extreme states and can also assume an intermediate state between the fully bent and fully extended conformation. It was further suggested that the extended conformation coincided with the activated integrin and that in the bent state, the integrin was resting. This model provided an attractive mechanism to account for activation of $\alpha_{IIb}\beta_3$ in particular and integrins in general.[299] However, in a subsequent crystal structure, a fibronectin fragment was observed bound to $\alpha_V\beta_3$ in a bent conformation.[300,301] Thus, even though $\alpha_{IIb}\beta_3$ may transition from bent to extended conformation, this change contributes to but may not be essential for ligand binding. Most likely, the integrin can exist in several conformational states that are in equilibrium; ligand binding is favored with the extended conformation of the integrin with an open headpiece but can occur with intermediate states, including forms that are still in a bent conformation.[298] From crystal structures of $\alpha_{IIb}\beta_3$, with or without bound ligands, differences are noted in the positioning of helices and in divalent ions in the β_3 A domain as well as movements of domains adjacent to the β_3 A domain. Movements of these structural elements may locally regulate ligand binding.[282]

Talin, a large (270 kDa) cytoskeletal protein, has been strongly implicated in integrin activation.[302,303] It is composed of a *N*-terminal FERM-like domain, the talin-head (talin-H) of about 47 kDa, and a long C-terminal rod domain.[304] Talin-H consists of three

subdomains, including the F3 subdomain, that resembles a phosphotyrosine binding (PTB) subdomain. This subdomain harbors the sites that interact with the β_3 cytoplasmic tail of integrins to induce integrin activation. In fact, talin-H interacts with two sites in the cytoplasmic tail of the β_3 subunit: the NPLY sequence in the midsegment of the cytoplasmic tail and a sequence in the membrane proximal region.[303,305-311] Talin binding to the membrane proximal site in the β_3 cytoplasmic tail displaces it from its complex with the α_{IIb} cytoplasmic tail, and this "unclasping" triggers integrin activation.[306,307,312,313] Mice containing point mutations in the talin-binding regions of β_3 exhibit a bleeding phenotype.[314,315] Talin-H also contains a membrane binding site, and interaction with the intermembrane region enhances the affinity of talin for the integrin, which is essential for activation. The talin rod harbors sites that mediate its interaction with the actin cytoskeleton. This linkage occurs either by direct binding to actin or indirectly through viculin or α-actinin.[316-318] These contacts allow talin to bridge between the integrin and the cytoskeleton of the cell, a linkage that is also critical for integrin induced outside-in signaling.

Intact talin exists in an autoinhibited state in unstimulated cells where interactions between the rod and talin-H domains prevent binding to the β_3-cytoplasmic tail. Talin becomes activated via several mechanisms, including binding of phosphoinositides[319] or RIAM (rap1 interacting adaptor molecule)[320] and by proteolytic cleavage by calpain.[302] Several other proteins are known to bind to the β_3 cytoplasmic tail. Some of these appear to compete with talin, thereby dampening integrin activation. Notable in this regard are Dok1, which bind to the NPLY sequence, and filamin, which binds to a more C-terminal site, but still inhibits integrin activation.[313,321-323]

Although studies in model systems, cells, and mice have established a pivotal role for talin in integrin activation,[324] it is evident that talin alone is not sufficient for integrin activation in physiologic settings.[325,326] Evidence from mice and humans has shown that the kindlin family members are also essential for integrin activation.[327-329] There are three kindlins in humans. Kindlin-1 deficiency in mice and humans results in a skin disease, Kindler syndromes, frequently associated with gastrointestinal problems.[330,331] Kindlin-2 deficiency has not been described in humans and is embryonically lethal in mice.[332,333] Kindlin-2 is the most broadly distributed of the kindlins. Kindlin-3 is particularly relevant to $\alpha_{IIb}\beta_3$ activation. It is found in hematopoietic cells and endothelial cells.[334,335] Its deficiency in mice leads to death shortly after birth, and the primary manifestations of its deficiency are bleeding, an inability to mount an inflammatory response, and osteopetrosis.[336] These same manifestations have been noted in the few reported cases of kindlin-3 deficiency in humans, although the penetrance of the abnormalities is variable. This deficiency is referred to as LADIII, LADI variant, or IADD (integrin activation deficiency disease).[328,329] In humans as well as in mice, the bleeding associated with kindlin-3 deficiency is a consequence of the inability of platelets to aggregate, which in turn arises from an inability to activate integrin $\alpha_{IIb}\beta_3$. The failure of leukocyte of transmigration reflects the inability to activate β_2 integrins, and the bone defects may be a consequence of an inability to activate one or both of these subfamilies of integrins. β_1 integrin activation can also be dysfunctional. Thus, the activation of at least three major integrin subfamilies is kindlin-3 dependent. In model cell systems, kindlins do not induce integrin activation but appear to cooperate with talin to enhance integrin activation (i.e., talin and kindlins are integrin co-activators).[325,326]

Kindlins exhibit many similarities with talin. Similar to talin, kindlins are FERM domain containing proteins, and like talin, the F_3 subdomain of kindlins interacts with integrin β subunits.[326,332,337] The unique signature of kindlins is the interruption of their FERM domains by an inserted plecksin homology (PH) domain. PH domains are frequently involved in lipid binding, and the PH domains of kindlins possess this function.[338,339] Thus, also similar to talin, kindlins interact with membranes, and the PH domain is not the only membrane binding site in kindlins. Distinct from talin is the sites within integrin β subunits that bind integrins.[326] As noted earlier, one of the talin binding sites in the β_3 cytoplasmic tail is the NPLY[747] sequence. Kindlin binding to the β_3-cytoplasmic tail involves the NITY[759], which is very close to the C-terminus of T[762]. Both tyrosine residues are targets for phosphorylation, which occurs as a consequence of ligand binding and outside-in signaling. Phosphorylation of Y[747] decreases, but does not preclude, talin binding[322]; phosphorylation of Y[759] prevents kindlin-2 binding to the β_3 cytoplasmic tail.[340] Although the role of talin in integrin activation by dissociation of the cytoplasmic tail complex is clear, the mechanism by which kindlins influence integrin activation remains to be resolved.

Several mechanisms can be envisioned to explain how fibrinogen binding to $\alpha_{IIb}\beta_3$ results in platelet aggregation. The simplest explanation is that a single fibrinogen molecule, by virtue of its dimeric structure, bridges two $\alpha_{IIb}\beta_3$ molecules symmetrically on adjacent platelets. Indeed, evidence can be cited to support this possibility.[341-343] Because multiple sites within each fibrinogen molecule can be recognized by $\alpha_{IIb}\beta_3$ (see later), asymmetric variations of direct bridging can be envisioned. Still another possibility is that changes subsequent to fibrinogen binding are required for platelet aggregation. Irreversible fibrinogen binding,[241] conformational changes in bound fibrinogen[216,344] and in occupied $\alpha_{IIb}\beta_3$,[345] clustering of fibrinogen/$\alpha_{IIb}\beta_3$,[346] and additional interactions of the receptor with the cytoskeleton of the cells[347-349] occur after initial binding of fibrinogen to platelets. Moreover, a series of intracellular signaling events is initiated and propagated as a result of receptor occupancy and platelet aggregation, including tyrosine and serine/threonine kinase and phosphatase activation.[291,292] These events are referred to as "outside-in" signaling. Whether such postreceptor occupancy events play a direct role in platelet aggregation is unknown, although circumstances have been described in which fibrinogen binds to $\alpha_{IIb}\beta_3$ without inducing platelet aggregation,[291] and mice with mutations in the tyrosine phosphorylation sites in the β_3 subunit exhibit reduced thrombus stability,[350] which implies a role for outside-in signals in platelet aggregation.

Recognition Specificity and Antagonism of $\alpha_{IIb}\beta_3$

Linear amino acid sequences define the recognition specificity of $\alpha_{IIb}\beta_3$ (Table 127-5). One peptide corresponds to the extreme COOH-terminus of the γ chain,[341,351] one of the three constituent chains of fibrinogen. The recognized amino acid sequence may involve only six amino acid residues.[352] The second peptide includes four amino acids and contains the following three amino acids in sequence: arginyl-glycyl-aspartic acid (RGD).[353-356] RGD sequences occur on two sites within the Aα chains of fibrinogen.[357] RGD sequences are also found on a variety of other proteins, including several that bind to $\alpha_{IIb}\beta_3$. In addition, several other integrin receptors recognize RGD sequences within their ligands.[34,358-361] Thus, the RGD sequence is a broadly used recognition code in cellular adhesive reactions. RGD with specific flanking residues can react selectively with individual integrins, and it was one such peptide that was crystallized in complex with $\alpha_V\beta_3$.[280] By contrast, the γ-chain sequence appears to be unique to fibrinogen. Synthetic peptides containing either the γ-chain peptide sequence or the RGD sequence interact directly with $\alpha_{IIb}\beta_3$ and bind to the same or mutually exclusive sites within the receptor.[362,363] Crystal structures of $\alpha_{IIb}\beta_3$ with mimetics of these two

peptide sequences suggest a similar binding mechanism,[282] but allosteric effects of additional binding sites cannot be excluded,[364] and allosteric inhibitors of ligand binding to integrins have been identified.[365] The preponderance of evidence indicates that the COOH-terminus of the γ chain is critical for fibrinogen binding to $\alpha_{IIb}\beta_3$.[366-368] Nevertheless, in the design of $\alpha_{IIb}\beta_3$ antagonists, the RGD sequence has often served as the starting compound because of its smaller size.[369] Identification of these two sequences does not exclude the possibility that other sequences are involved in fibrinogen binding to $\alpha_{IIb}\beta_3$. Indeed, there is evidence supporting this concept.[370]

Fibrinogen is not the only ligand that binds to $\alpha_{IIb}\beta_3$. Several other adhesive proteins that can serve as ligands are listed in Table 127-2. All of these adhesive proteins contain at least one RGD sequence, and RGD peptides interfere with the binding of fibronectin[353,356] and vitronectin[371] to platelets. Because plasma fibrinogen concentrations are 10-fold higher than its dissociation constant for $\alpha_{IIb}\beta_3$, under physiologic conditions, the receptor is nearly saturated with fibrinogen. Thus, fibrinogen is the dominant ligand for $\alpha_{IIb}\beta_3$ in this environment. However, all of these ligands, except fibrinogen, are found in subendothelial cell matrices, and these other interactions may dominate in this microenvironment. Because vWF is bound to platelets via GPIb-V-IX, it resides in close proximity to $\alpha_{IIb}\beta_3$ on the platelet surface, and this proximity may favor its engagement by $\alpha_{IIb}\beta_3$. In addition to its role in platelet aggregation, $\alpha_{IIb}\beta_3$ may also be involved in platelet adhesion, particularly in stabilizing cell–matrix interactions.[372] It may be in this latter function that other $\alpha_{IIb}\beta_3$ ligands play a key role. Thrombospondin-1 associates with the surface of resting and stimulated platelets.[373-375] On the surface, it plays an auxiliary role in platelet aggregation by stabilizing platelet aggregates.[376] This activity may arise from its capacity to bind to fibrinogen.[181,377] Several candidate receptors for thrombospondin have been proposed,[348,378-381] and the interaction may be mediated by a complex of several of these candidate receptors, including CD36, integrin-associated protein, and $\alpha_{IIb}\beta_3$.[382] Complexation of $\alpha_{IIb}\beta_3$ with other platelet membrane proteins CD9,[383-385] CD40L,[255] and Gas6[166] also may play a role in controlling its activation and ligand-binding functions and platelet responses in general. Increasing evidence indicates that a number of these and other membrane proteins in platelets influence the adhesive responses of platelets in vitro and in vivo.[386]

Throughout the 1980s, a number of compounds were described that bound to $\alpha_{IIb}\beta_3$ and inhibited platelet aggregation. Furthermore, it was noted that bleeding in patients with Glanzmann thrombasthenia tended to be relatively mild. Taken together, these observations prompted the notion that $\alpha_{IIb}\beta_3$ would be and attractive target for antiplatelet drugs. Antagonists included monoclonal antibodies, small peptide ligands, and nonpeptidic ligand mimetics. Representatives of these classes of antagonists were evaluated in various animal models of thrombosis and in large clinical trials.[387-394] Three such agents, all intravenous drugs, ultimately were approved for patient usage by U.S. Food and Drug Administration. Abciximab is a Fab fragment of a humanized monoclonal antibody; eptifibitide is a cyclic peptide based on the sequence of a snake venom peptide; and tirofiban is a nonpeptide that was designed with RGD as a starting structure (see Chapter 148). Although all three $\alpha_{IIb}\beta_3$ antagonists continue to be used, particularly in patients undergoing primary percutaneous coronary interventions for acute myocardial infarction, the need for $\alpha_{IIb}\beta_3$ antagonists has declined with the introduction of more potent oral antiplatelet drugs.[395-398] There was great optimism that orally active $\alpha_{IIb}\beta_3$ antagonists would be of benefit. A number of drugs were developed with excellent pharmacokinetic properties. However, when tested in clinical trials, they proved to be ineffective or even detrimental.[399] The reason for the failure of these oral antagonists is not fully understood. One explanation is that patients were underdosed to avoid safety issues, but this would not in itself explain the detrimental effects. It has also been suggested that these drugs may leave $\alpha_{IIb}\beta_3$ in an activated state when they dissociate from the receptor.[400] Regardless of the explanation, the initial clinical trials dampened the effort to develop orally active $\alpha_{IIb}\beta_3$ antagonists, and all such programs were abandoned.

CHAPTER 128

MOLECULAR BASIS OF BLOOD COAGULATION

Kathleen Brummel-Ziedins and Kenneth G. Mann

Blood is the principal vehicle delivering oxygen and nutrients to the various tissues and organs of the body. Blood flow and the integrity of the vasculature are essential to life itself. The hemostatic process has evolved to provide damage recognition and protection from blood loss after perforation of the vasculature while at the same time preventing the systemic activation of the clotting system. However, pathologic occlusions are associated with dysregulation of the intravascular system, resulting in venous or arterial thrombosis. The fine line between vascular occlusion and hemostasis is defined by the complex interplay between pro- and anticoagulant materials provided by the blood, the vasculature, and subvascular elements. The appropriate functions occur as a consequence of intense focal development and regulation of enzymatic activity at sites of vascular injury.

The development of the inventory of components involved in plasma clotting were initially based on the most abundant procoagulant plasma proteins, notably prothrombin and fibrinogen, and extended during the past century with the identification of genetic abnormalities that led to bleeding and deviations in laboratory tests that evolved as the inventory of congenital defects expanded. In some instances, laboratory test results indicating a defect in the procoagulant system were not mirrored by hemostatic pathology. In a similar fashion, the congenital defects associated with thrombosis led to discovery of anticoagulant proteins in blood and vascular counterparts associated with their presentation and activation.

The functional connections between procoagulant "factors" were developed by mixing and matching plasmas associated with different hemostatic disorders. This inventory and its connectivity were ratified and expanded by experiments performed with transgenically mutated mice.

The dynamics of the plasma coagulation process as expressed are a consequence of the molar concentrations of the pro- and anticoagulant components in blood and the vasculature and the kinetic processes associated with the dynamics of both the activation and functions of the various proteins associated with the process.

The initial result of the activation of the procoagulant hemostatic process is the formation of a fibrin–platelet plug that forms the temporary seal of the vascular perforation in hemostasis. The generation of an occlusive fibrin–platelet plug blocking further flow through an element of the vasculature is thrombosis. In both instances, the fibrin–platelet scaffold is ultimately removed and substituted by vascular repair, new cells, and connective tissue. In thrombosis, the platelet–fibrin plug is removed mechanically or by biochemical intervention to restore flow to the flow-starved vascular bed.

The elements of clotted fibrinogen–platelet plug are dissolved by the fibrinolytic system, a tightly regulated dynamic system involving enzyme activation, feedback regulation, and blockade by a potent series of inhibitors. Just as there is an interplay between the pro- and anticoagulant components that brings about a blood clot in hemostasis, similar mechanisms occur when blood clots are dissolved via the fibrinolytic process, which is essential for tissue repair. This review describes the components of the pro- and anticoagulant system and the pro- and antifibrinolytic system and the interplay between these systems. The common feature of both systems is the focal presentation of activity that is dependent on the presentation of surface bound enzymatic complexes that can cleave their respective substrates.

Blood coagulation can best be understood if viewed as a choreographed system that starts from an inventory of the key players, the relationship or connectivity of these players, and the dynamic catalytic processes. These processes together keep blood in a fluid state but primed to react to vascular injury in an explosive manner. Therefore, following sections describe the process of blood coagulation in terms of the inventory, the connectivity, and then the dynamics.

INVENTORY: PROCOAGULANT, ANTICOAGULANT AND FIBRINOLYTIC PROTEINS, INHIBITORS AND RECEPTORS

Putting together an inventory of the blood coagulation components is still an ongoing process, but what we currently know to date began from initial observations that were made in the fifth century and recorded in the Babylonian Talmud. It was noted that if two male children died of bleeding after circumcision, the third should not be circumcised.[1] Over the centuries, many more hypotheses were made regarding what happens to blood when it escapes from the body.[2,3] The realization that clots stem blood loss only occurred in the 18th century.[2,3] The existence of thrombin, the key enzyme in blood coagulation, was recognized in the 19th century.[2,4]

In 1905, Paul Morawitz proposed the classic theory of coagulation.[5] He hypothesized that in the presence of calcium and thromboplastin, prothrombin was converted to thrombin, which in turn converted fibrinogen to the fibrin clot. These clotting factors were subsequently assigned Roman numerals, factor I (fibrinogen), factor II (prothrombin), factor III (thromboplastin; tissue factor membrane), and factor IV (calcium).[6] As more coagulation factors were introduced, they were assigned consecutive Roman numerals. The activated forms are distinguished by a lower case "a" after their Roman numeral designation. Therefore, the activated form of factor V becomes factor Va.

More complex descriptions of the coagulation system were as a "cascade" or "waterfall". Macfarlane[7] and Davie and Ratnoff[8] proposed that in an intrinsic pathway, involving only plasma, blood coagulated by a sequence of events in which the reactions occurred in a defined series leading to fibrin clot formation. Over the past 6 decades, the Morawitz/Davie and Macfarlane pathways have been significantly expanded (Fig. 128-1). Each reaction shares a similar mechanism in which an inactive zymogen protein is converted to an active enzyme and each "enzyme" is a surface bound multiprotein complex consisting of a surface, divalent calcium ions (Ca^{2+}), a protease, and a cofactor. Although some facets of these initial descriptions are still valid, the emerging concept of coagulation and fibrinolysis centers on a complex network of highly interwoven concurrent processes. Procoagulant and fibrinolytic events occur simultaneously with many positive and negative feedback loops regulating the processes.

To fully understand the multiple simultaneous processes that occur to effect a hemostatic response, we will first inventory the key procoagulant, anticoagulant, and fibrinolytic participants. The inventory sections discuss vitamin k–dependent protein family,

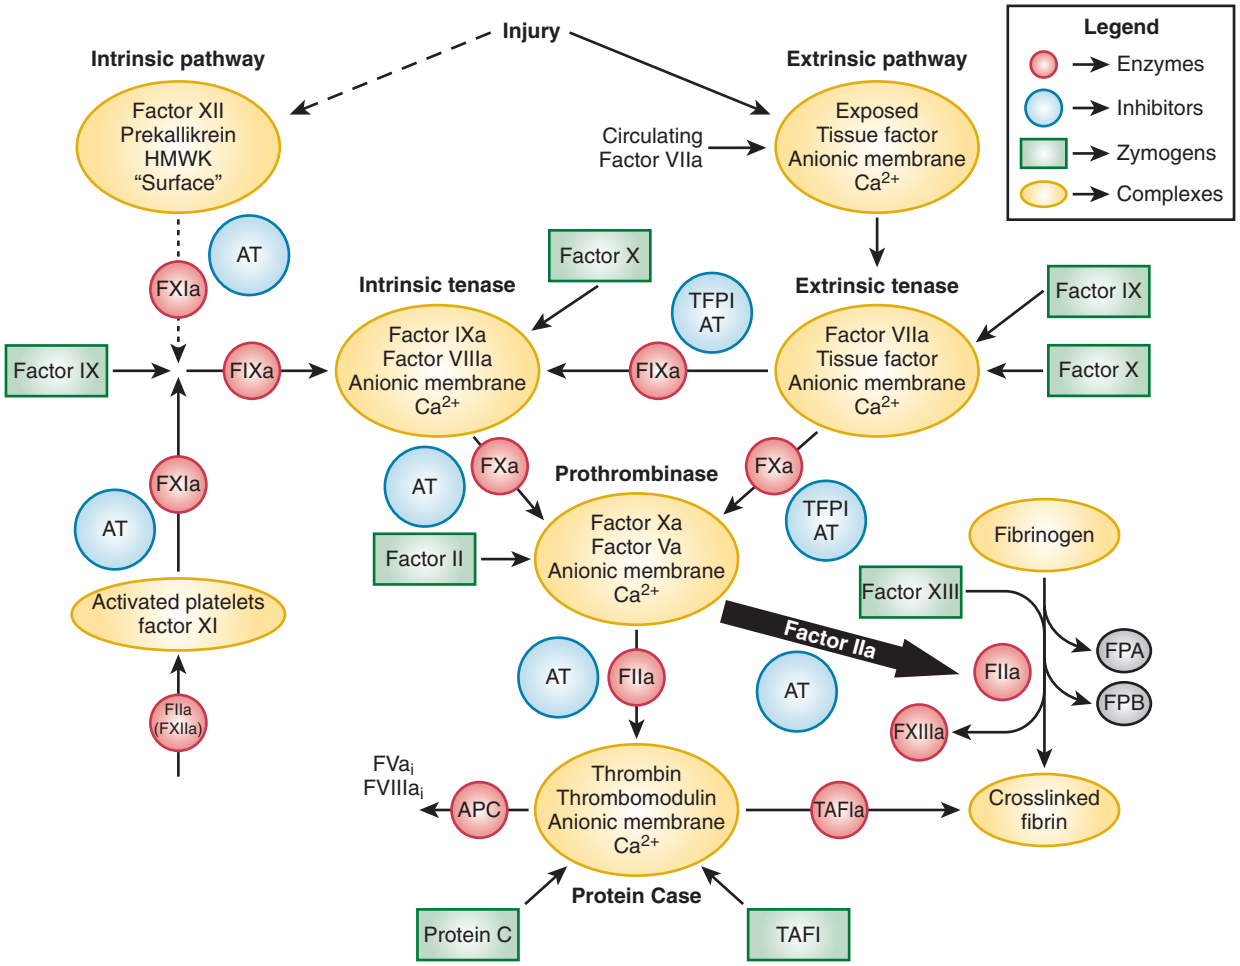

Figure 128-1 OVERVIEW OF HEMOSTASIS. Coagulation is initiated via two pathways, the primary extrinsic pathway *(right)* and the accessory (historically called the *contact* or *intrinsic pathway*) *(left)*. An illustration of the multistep processes are as follows: enzymes *(small circles),* inhibitors *(large circles),* zymogens *(boxes),* or complexes *(ovals)*. The accessory pathway has no known bleeding etiology associated with it; thus, this path is considered accessory to hemostasis. Upon injury to the vessel wall, tissue factor, the cofactor for the extrinsic tenase complex, is exposed to circulating factor VIIa and forms the vitamin K–dependent complex extrinsic tenase. Factor IX and factor X are converted to the serine proteases factor IXa (FIXa) and factor Xa (FXa), which then form the intrinsic tenase and prothrombinase complexes, respectively. The combined actions of intrinsic and extrinsic tenase and the prothrombinase complexes lead to an explosive burst of thrombin (IIa). Thrombin not only functions as a procoagulant but also acts as an anticoagulant when complexed with the cofactor thrombomodulin in the protein Case complex. The product of the protein Case reaction, activated protein C (APC), inactivates the cofactors factors Va and VIIIa. The cleaved species, factors Va_i (FVa_i) and $VIIIa_i$ ($FVIIIa_i$), no longer support the respective procoagulant activities of the prothrombinase and intrinsic tenase complexes. When thrombin is generated through procoagulant mechanisms, thrombin cleaves fibrinogen, releasing fibrinopeptides A and B (FPA and FPB, respectively), and activates factor XIII to form a cross-linked fibrin clot. Thrombin–thrombomodulin also activates thrombin-activatable fibrinolysis inhibitor (TAFI), which delays fibrin degradation by plasmin. The procoagulant response is downregulated by the stoichiometric inhibitors tissue factor pathway inhibitor (TFPI) and antithrombin (AT). TFPI serves to attenuate the activity of extrinsic tenase, the trigger of coagulation. AT directly inhibits thrombin, FIXa, and factor Xa. The accessory pathway provides an alternate route for the generation of factor IXa. Thrombin has also been shown to activate factor XI. *HMWK,* High-molecular-weight kininogen.

cofactor proteins, the intrinsic accessory pathway proteins, endothelium, platelets, proteinase inhibitors, clot proteins, and fibrinolysis proteins.

The Vitamin K–Dependent Protein Family

Vitamin K–dependent proteins, synthesized in the liver, play a central role in blood coagulation through either procoagulant or anticoagulant mechanisms. The vitamin K–dependent protein family includes the zymogen procoagulant factors VII, IX, X, and prothrombin and the anticoagulants protein C, protein S, and protein Z (Fig. 128-2 and Table 128-1). Except for protein S and protein Z, after cleavage to their active forms these proteins are serine proteases related to the trypsin and chymotrypsin superfamily. Peptide bond cleavage at specific sites converts the vitamin K–dependent zymogens to their active serine protease forms. All share noncatalytic domains, each of which is characterized by highly conserved regions that fold, independently from the rest of the molecule, into a characteristic three-dimensional shape. The domains of the vitamin K–dependent proteins are illustrated in Fig. 128-2. Several reviews have been written on vitamin K–dependent proteins.[9-11]

Vitamin K is essential for the biosynthesis of these clotting factors by participating in the cyclic oxidation and reduction of the enzyme that converts 9 to 13 amino-terminal glutamate residues to γ-carboxy glutamate (Gla; see Fig. 128-2) (for reviews, see References 9 and 12-14). This posttranslational modification to form Gla residues adds a net negative charge to the molecules that enables the vitamin

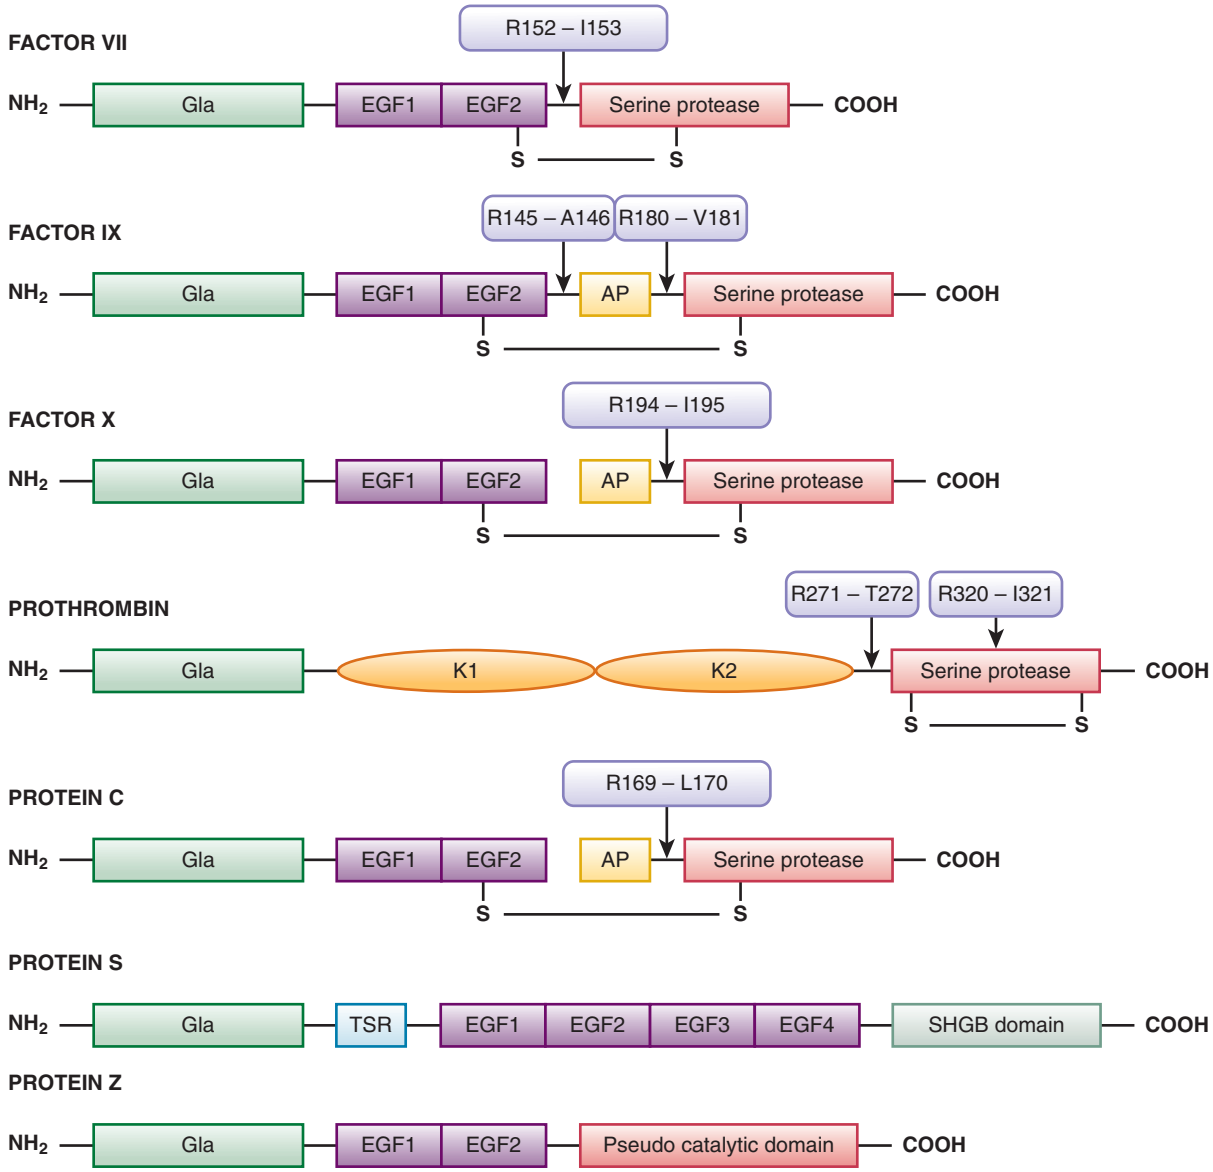

Figure 128-2 SCHEMATIC REPRESENTATION OF THE VITAMIN K–DEPENDENT PROTEINS. The vitamin K–dependent proteins can be divided into two classes, procoagulant (factors II, VII, IX, and X) and anticoagulant (protein C, protein S, and protein Z). The building blocks for these proteins include an NH_2-terminal Gla domain, consisting of nine to 13 Gla residues, followed by either an epidermal growth factor (EGF)–like domain in factor VII, factor IX, factor X, protein C, protein S, and protein Z or a kringle (K) domain in prothrombin. In protein S, a thrombin-sensitive region (TSR) precedes the EGF domain. Active sites are contained within the serine protease domain. Cleavage sites for the conversion of zymogens to their active forms are designated by *arrows;* activating proteases are placed in *boxes* above the *arrows*. Factor IX, factor X, and protein C are activated by proteolytic removal of an activation peptide (AP). Protein S, which is not a serine protease precursor, contains a sex hormone–binding globulin–like domain (SHGB) at the COOH-terminus. Protein Z also contains a "pseudo catalytic domain" in the COOH- terminus and does not function as a serine protease. Disulfide bonds (-S-S-) critical to the integrity of the two-chain zymogens or active forms are presented.

K–dependent proteins to interact with Ca^{2+} and a membrane surface.[15,16] Blocking the formation of the Gla residues is the basis for anticoagulant therapy with coumarin (warfarin) derivatives, such as warfarin, which are chemically similar in structure to vitamin K (Fig. 128-3). The Ca^{2+} binding association with this modification is also the basis for the anticoagulant activity of sodium citrate, a calcium chelator, found in the blue top vacuum tubes used for clinical laboratory testing of clotting activity. The level of inhibition achieved with the same dose of warfarin varies among patients. Increased sensitivity to warfarin has been identified in patients when started after surgery.[17,18] Factors affecting the level of anticoagulation include dietary intake of vitamin K; liver function; concomitant medications that either reduce or enhance the warfarin effect[19]; common polymorphisms in the vitamin K epoxide reductase complex subunit 1 (VKORC1), which is responsible for vitamin K reduction; and polymorphisms in CYP2C0, which affect warfarin metabolism (for reviews, see References 20 and 21). Therefore, genotyping may be helpful to personalize starting doses of warfarin. Ultimately, proper monitoring of warfarin therapy is essential. This is done using the prothrombin time (PT) with the assay sensitivity corrected using the international normalized ratio.[22,23]

The NH_2-terminal Gla domains are followed by either a kringle domain in factor II or an epidermal growth factor–like domain (EGF) in factor VII, factor IX, factor X, protein C, protein S, and protein Z (see Fig. 128-2). Protein S is not a serine protease precursor and instead contains a thrombin-sensitive region before the EGF

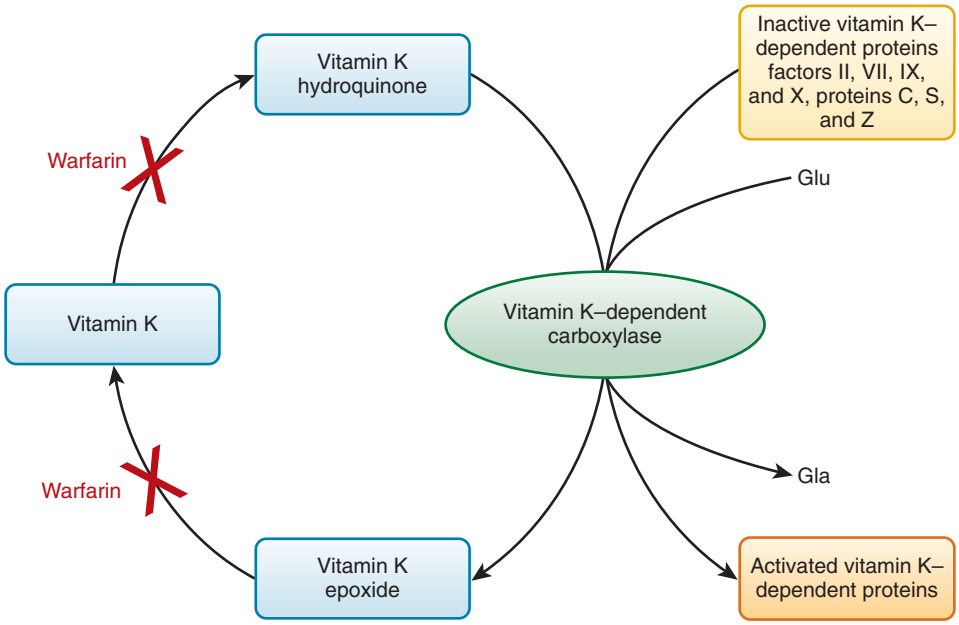

Figure 128-3 VITAMIN K–DEPENDENT PROCESS AND WARFARIN EFFECT. Schematic representation of the mechanism of γ-carboxy glutamate (Gla) generation by a vitamin K–dependent reaction cycle to produce an active protein is illustrated. The regeneration of vitamin K hydroquinone by the vitamin K–dependent reductases is inhibited by warfarin.

domain and a sex hormone–binding globulin–like domain (SHBG) in the COOH- terminus.[24] Protein Z contains a "pseudo catalytic domain" in the COOH- terminus and does not function as a serine protease enzyme.[25]

Vitamin K–dependent protein complexes are essential for establishing hemostatic balance (Fig. 128-4). Each complex is composed of a serine protease enzyme, a cofactor that functions as a surface receptor or enhancer for the enzyme Ca^{2+}, and a negatively charged membrane surface provided by activated or damaged cells (e.g., endothelial cells, monocytes, and platelets). There are four vitamin K–dependent complexes: the extrinsic tenase complex (factor VIIa–tissue factor), the intrinsic tenase complex (factor IXa–factor VIIIa), the prothrombinase complex (factor Xa–factor Va), and the anticoagulant protein Case complex (thrombin–thrombomodulin).

When the serine protease is associated with its respective cofactor on an appropriate membrane surface with Ca^{2+}, the specific reactions occur at a rate that is 10^4 to 10^9 fold faster than that of protease–substrate combination alone.[26] One way to visualize the importance of the assembly of these macromolecular complexes in the formation of the hemostatic plug is to note that if a healthy person takes 4 minutes for his or her blood to clot, then in the absence of membrane and cofactor, blood clot formation would take approximately 3.8 years.

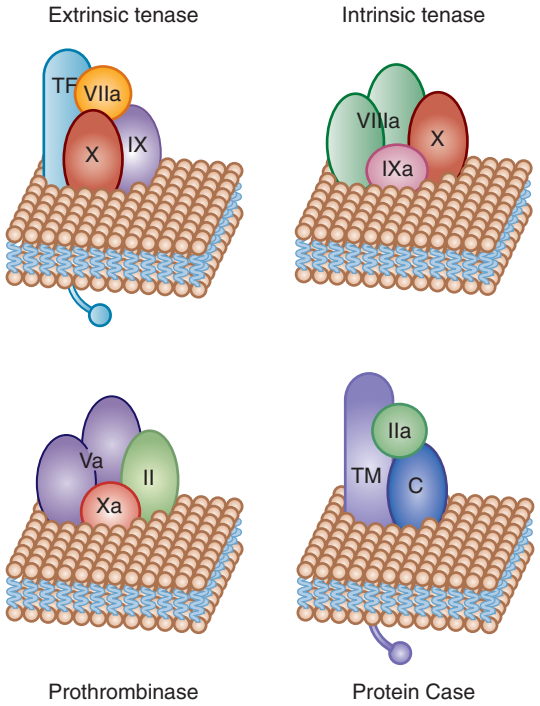

Figure 128-4 VITAMIN K–DEPENDENT COMPLEXES. Three procoagulant complexes (extrinsic tenase, intrinsic tenase, and prothrombinase) and one anticoagulant complex (protein Case) are illustrated. Each membrane complex consists of a vitamin K–dependent serine protease (factor VIIa [VIIa], factor IXa [IXa], factor Xa [Xa], or thrombin [IIa]) and a soluble or cell surface–associated cofactor (factor VIIIa [heavy and light chain $VIII_H$ and $VIII_L$], factor Va [heavy and light chain V_H and V_L] tissue factor [TF], or thrombomodulin [TM]). Each serine protease is shown in association with the appropriate cofactor protein and zymogen substrate(s) on the membrane surface. The membrane serves as a scaffold for the coagulation reactants, enhancing the reaction rates by 10^4- to 10^9-fold.

Cofactor Proteins

There are two categories of procoagulant cofactor proteins; the cell-bound cofactors (tissue factor and thrombomodulin) and the soluble plasma-derived procoagulant procofactors (factor V and factor VIII with its circulating carrier von Willebrand factor [vWF]).

Cell-Bound Cofactors

Tissue Factor

Tissue factor is a transmembrane protein that functions as a nonenzymatic cofactor for factor VIIa in the extrinsic tenase complex[27] (for reviews, see References 28 and 29) (Fig. 128-5, *A*). In the absence of injury or inflammatory stimuli, tissue factor is not expressed on cellular surfaces in direct contact with circulating blood (for a review,

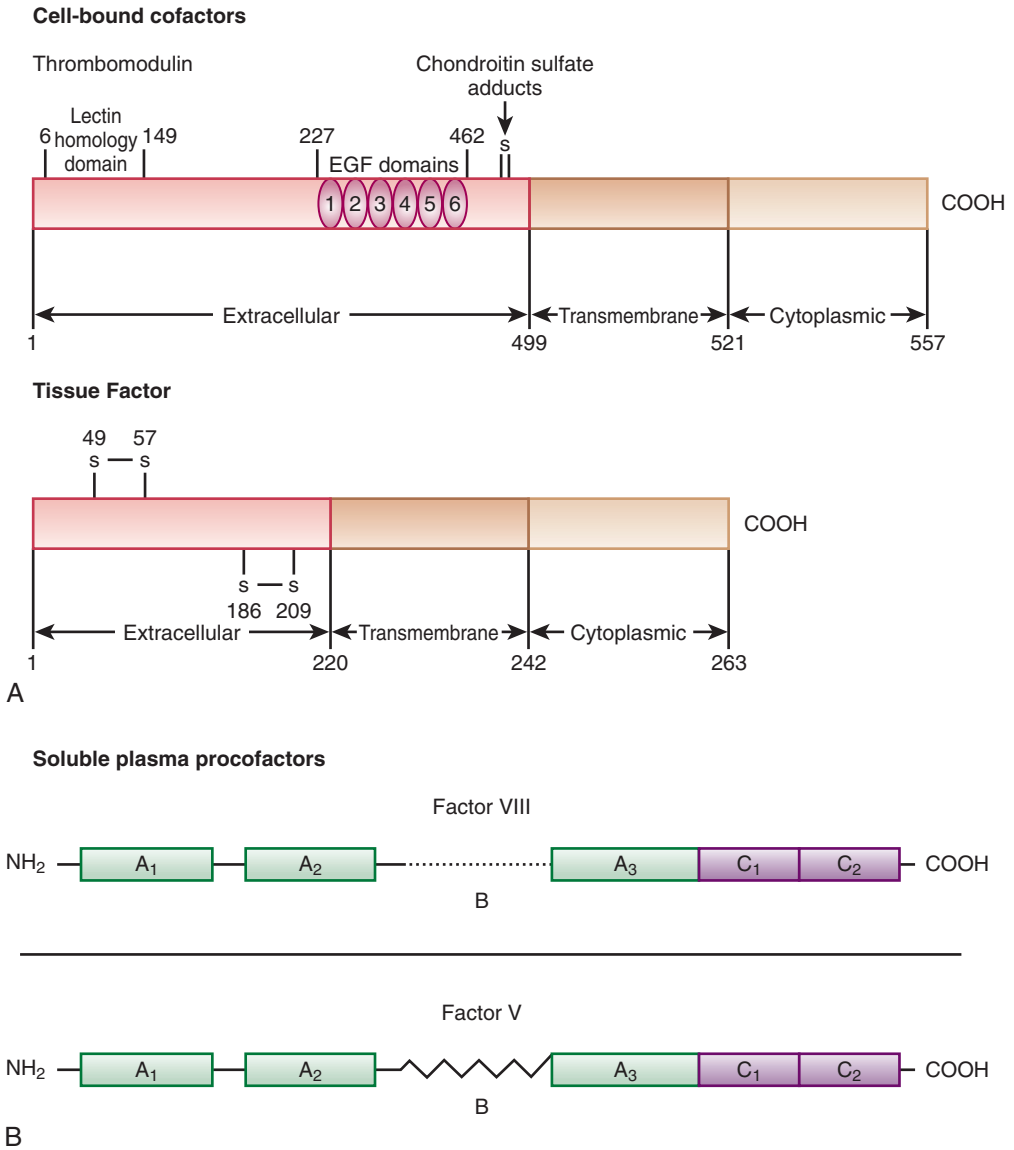

Figure 128-5 CELL-BOUND AND SOLUBLE COFACTOR STRUCTURES. **A,** Cell-bound cofactors: tissue factor and thrombomodulin. Tissue factor is composed of an extracellular domain (residues 1-219), a transmembrane domain (residues 220-242), and a cytoplasmic domain (residues 243-263). Two disulfide bonds (S-S) and the sites of the three carbohydrate moieties (CHO) are identified by amino acid residue. One cysteine (C^{245}) contains a thiol ester linkage to a fatty acid. Tissue factor, which is the cofactor for factor VIIa in the extrinsic tenase complex, is exposed on the subendothelial surface after injury. Thrombomodulin is an endothelial cell-surface glycoprotein composed of five distinct domains. These include a lectinlike domain (residues 6-149), a domain containing six epidermal growth factor (EGF)–like regions (residues 227-462), a small extracellular domain rich in threonine and serine residues (S^{472} and S^{474} have been identified as sites of chondroitin sulfate adducts), a membrane-spanning region (residues 499-521), and a cytoplasmic tail (residues 522-557). There are nine known glycosylation sites (CHO) on the thrombomodulin molecule. Thrombomodulin functions as the cofactor in the protein Case complex and assists in the generation of activated protein C. **B,** Soluble plasma procofactors: factor VIII and factor V. The linear domain structures (A1-A2-A3-C1-C2) are illustrated with *horizontal arrows* bracketed by the beginning and ending amino acid number. Thrombin (IIa) and activated protein C (APC) cleavage sites are shown with *vertical arrows*. The B regions (factor V, residues 709-1545; factor VIII, residues 740-1689) are represented by the *cross-hatched regions*.

see Reference 30). Presentation of tissue factor to the circulation is the event that triggers the primary procoagulant pathway of coagulation[31-33] (see Fig. 128-1). There are no known mutations or deficiencies of human tissue factor, and tissue factor deletion in mice is lethal during embryonic development,[34] leading to the speculation that tissue factor is essential for life.

Tissue factor activity is primarily regulated by controlling its presentation. The commonly accepted sources of functional tissue factor are the subendothelium exposed upon vascular damage or monocytes stimulated by cytokines. However, there is controversy regarding the source and presentation of active tissue factor and whether functional tissue factor circulates in blood in healthy and pathologic states.[35-40] Microparticles (bloodborne tissue factor) are generally defined as submicron-sized cell-derived membrane fragments produced in response to activation or apoptosis. Its role in hemostasis is still debated.[28,35,41,42]

Thrombomodulin

Thrombomodulin is a type 1 transmembrane protein constitutively expressed on the surface of vascular endothelial cells (see Fig. 128-5, *A*). Thrombomodulin is a high-affinity receptor for all thrombin forms and acts as a cofactor for the thrombin-dependent activation of protein C.[43] The endothelial cell protein C receptor (EPCR) provides cell-specific binding sites for both protein C and activated protein C (APC).[44-47] When bound to thrombomodulin, thrombin's procoagulant activities (e.g., its capacity to generate fibrin, and activate factor V, factor VIII, factor XI, and platelets) are neutralized, and the rate of inactivation of thrombin by antithrombin is increased.[48-50] The generation of APC by the thrombin–thrombomodulin complex leads to the inactivation of the procoagulant cofactors, factor Va and factor VIIIa, thus suppressing thrombin formation.[51,52] Thrombin–thrombomodulin, or the protein Case (see Fig. 128-4) complex, also has an antifibrinolytic role via the activation of the fibrinolysis inhibitor, thrombin activatable fibrinolysis inhibitor (TAFI) (for reviews, see References 53-56).

Thrombomodulin activity on the surface of endothelial cells is decreased by inflammatory cytokines,[57,58] and this decrease may contribute to the hypercoagulation characteristic of inflammatory states.

Soluble Plasma Procofactors

Factor V

Factor V is a large single-chain glycoprotein (GP) that circulates in human plasma (see Table 128-1 and Fig. 128-5, *B*) and is also contained in the α-granules of human platelets, with approximately 18% to 25% of the total factor V found in platelets.[59] The procofactor factor V is proteolyzed by α-thrombin to the active cofactor factor Va.[60] Factor Va functions both as a factor Xa receptor and positive modulator of factor Xa catalytic potential in the prothrombinase complex (see Fig. 128-4).[61] Factor Va is proteolytically inactivated by activated protein C (APC).[62,63] The importance of this regulatory mechanism is demonstrated by the "APC resistance" syndrome associated with factor V^{Leiden}.[64,65] Individuals with factor V^{Leiden} have a G to A substitution at nucleotide 1691 in the factor V gene that results in an Arg^{506}→Gln mutation at the protein level.[66] Factor Va^{Leiden} has normal cofactor activity as part of the prothrombinase complex. However, unlike normal factor Va, factor Va^{Leiden} is more slowly inactivated by APC. The Arg^{506}→Gln mutation hinders the first step in the series of inactivating cleavages by APC. Cleaved factor Va^{Leiden} retains limited cofactor activity and continues to promote thrombin generation. The identification, role in coagulation, and overall importance of factor V in hemostasis have been described in numerous reviews.[61,67]

Factor VIII

The soluble procofactor factor VIII, or antihemophilic factor (see Fig. 128-5, *B*), circulates in plasma in complex with the large multimeric protein vWF.[68] vWF acts to regulate the plasma concentration of factor VIII. Factor VIII interaction with vWF requires the NH_2^- and $COOH^-$ termini of the factor VIII light chain (A3, C1, and C2 domains), although a specific vWF-binding site has been identified at residues 1673 to 1684 on the light chain.[68-71] Factor VIII is activated by thrombin cleavage at three sites (Arg^{372}, Arg^{740}, Arg^{1689}) to generate the heterotrimeric cofactor factor VIIIa.[72] The vWF-binding site is removed from the factor VIII protein by thrombin cleavage at Arg^{1689}. After forming, vWF–free factor VIIIa forms a complex with the serine protease factor IXa, Ca^{2+} and a membrane (provided by platelets), resulting in the intrinsic tenase (see Fig. 128-4). Factor VIIIa function is downregulated by the relatively rapid dissociation of the noncovalently associated A2 subunit, which is produced by the cleavages required for activation. Factor VIII is homologous (40% identity) to the procofactor factor V.[73]

Deficiency of factor VIII, or hemophilia A, is a well-characterized bleeding disorder linked to the X chromosome.[74] Hemophilia A, therefore, occurs almost exclusively in males at a frequency of one in 5000 to one in 10,000 males.[75]

Von Willebrand factor

von Willebrand factor has several key roles in coagulation and is also contained in the α-granules of human platelets.[76] vWF is a large adhesive GP that circulates in plasma as a heterogeneous mixture of disulfide-linked multimers that range in size from dimers (M_r = 600,000) to extremely large multimers of more than 20 million KDa. vWF has binding sites for factor VIII, heparin, collagen, platelet GPIb, and platelet GPIIb-IIIa.[77-90] vWF acts as the bridge between platelets to promote platelet aggregation. The primary platelet binding site for vWF is the GPIb-IX-V receptor complex. GPIb-IX-V is an active receptor on unstimulated platelets and serves to promote platelet aggregation and adhesion to vWF in the absence of platelet activation.[91]

von Willebrand factor is a structural protein and is part of the subendothelial matrix. Endothelial cells secrete vWF multimers, which are larger than those found circulating in plasma.[92] The function of these large multimeric forms of vWF is to bind to and agglutinate blood platelets under high shear conditions. These large multimers of vWF are degraded by a specific metalloprotease called a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13 (ADAMTS)-13.[93-95] In familial and acquired thrombotic thrombocytopenic purpura, ultra-large vWF multimers are correlated with defective ADAMTS-13 activity.[96]

ABO blood type has a significant influence on vWF levels, with individuals of types A, B, or AB blood having much higher levels of vWF than those with type O blood.[97,98] vWF is also known for its role in ristocetin-induced platelet agglutination,[99,100] which is the basis of clinical assays for von Willebrand disease, a fairly common disorder that is estimated to occur in 1% to 2% of the general population (see Chapter 140).[101-104] vWF is also an acute phase reactant, and vWF levels are elevated as a result of stress, pregnancy, or surgical trauma.[105-108]

The Intrinsic Accessory Pathway Proteins

The designation "intrinsic accessory pathway" emerged as the relationship between genetic deficiencies and bleeding phenotypes was established (see Fig. 128-1). Deficiencies of proteins associated with the intrinsic or accessory pathway (factor XII, prekallikrein, and high-molecular-weight kininogen [HMWK]) are not ordinarily associated with excessive bleeding, even after surgical challenge.[109-111] In contrast, deficiencies of the protein components of the extrinsic or primary pathway (prothrombin and factors V, VII, VIII, IX, and X) can lead to severe bleeding diatheses.[112-116] The physiologic role of the accessory pathway is therefore not clearly understood.[117]

Although the intrinsic pathway proteins have no defined role in normal hemostasis, these accessory pathway factors are thought to play a key role in disseminated intravascular coagulation (DIC) associated with the systemic inflammatory response syndrome[118,119] and in the promotion of thrombus stability[117,120,121] and may be a new target to control pathologic coagulation.[122] Also, the accessory pathway is important in cardiopulmonary bypass because of contact between blood components and synthetic surfaces.[119] Recent evidence suggests that biologic activation of the contact pathway system may be accomplished through assembly of these proteins on endothelial cell membranes and that prekallikrein is activated by an endothelial cell membrane cysteine protease rather than by factor XII.[123,124] Extracellular RNA derived from damaged or necrotic cells has also been found to participate in the activation of proteases of the contact pathway by providing a procoagulant cofactor template for factor XII- or XI-induced contact activation.[125] Polyphosphates, linear inorganic polymers of 60 to 100 phosphate residues, released from platelets have also been shown to activate fXII.[126]

In principle, factor XI represents an intersection point for the two pathways. Individuals with factor XI deficiency (hemophilia C) have a variable bleeding phenotype upon surgical challenge,[127,128] therefore establishing an essential role for factor XI in hemostasis. During the coagulation process, factor XIa formation appears to be catalyzed by thrombin as part of a positive feedback loop stemming from

thrombin generation.[129] Factor XIa then functions in the propagation phase of thrombin generation in association with the primary pathway by activation of factor IX.[130]

Three proteins, factor XII, prekallikrein, and HMWK, are required for activity of the intrinsic or accessory pathway. Factor XII and prekallikrein are zymogens that are activated to generate serine proteases, and HMWK is a nonenzymatic procofactor (Fig. 128-6). The activation of this pathway in vitro is accomplished when factor XII autoactivates to factor XIIa upon exposure to foreign surfaces, including kaolin, dextran sulfate, and sulfatides.[131-133] The substrates for factor XIIa, prekallikrein, and factor XI exist in noncovalent complex with HMWK and become activated to kallikrein and factor XIa, respectively.[134] Positive feedback loops exist in which kallikrein cleaves HMWK, thereby releasing bradykinin and allowing more prekallikrein and factor XI to associate and activate.[135] This pathway is also negatively regulated by the cleavage of HMWK by factor XIa.[136]

Proteinase inhibitors

Proteinases, enzymes that hydrolyze peptide bonds, are found in a wide array of biologic systems, including the blood coagulation process (clot formation and fibrinolysis), digestive system, apoptotic cascades, and the immune system. To keep these systems in balance between activation and inhibition, a complex system of proteinase inhibitors has evolved. In blood, proteinase inhibitors constitute a significant percentage of circulating proteins. In general, proteinases that activate the coagulation and fibrinolytic cascades have highly defined substrate specificities. Coagulation is kept in check through the action of several specific and broad-spectrum proteinase inhibitors. Specific clot formation inhibitors are antithrombin, tissue factor pathway inhibitor (TFPI), heparin cofactor II, and protein C inhibitor. Together specific and broad-spectrum inhibitors function to localize, limit, and control hemostasis (see Chapter 129).

Antithrombin

Antithrombin is a member of the serpin proteinase inhibitory family and circulates in blood as a single-chain GP[137] (see Table 128-1; Fig. 128-7). Congenital antithrombin deficiency exhibits an autosomal dominant pattern of inheritance, with an incidence of 1 in 2000 to 1 in 5000.[138] Individuals with this deficiency have partial expression of antithrombin and are prone to venous thromboembolic disease.[139] The complete absence of antithrombin is lethal.

Antithrombin has a broad spectrum of inhibitory activity with most of its target proteases participating in the coagulation cascade (see Fig. 128-1). It is primarily an inhibitor of the serine proteases thrombin, factor Xa, factor IXa, factor VIIa–tissue factor, factor XIa, factor XIIa, kallikrein, and HMWK.[140-142] Heparin and heparan sulfate potentiate these reactions, and heparin is used for the prevention and treatment of thrombosis. When antithrombin is complexed with heparin, its rate of inhibition of several coagulation proteases is accelerated by up to 10,000-fold. The general mechanism of inhibition involves reaction of the active site of the enzyme with a peptide loop structure (the reactive center loop) of antithrombin, forming a tight, equimolar (1:1) complex. Inactivation proceeds through covalent bond formation between antithrombin and the protease followed by inactivating structural rearrangements of both antithrombin and the protease.

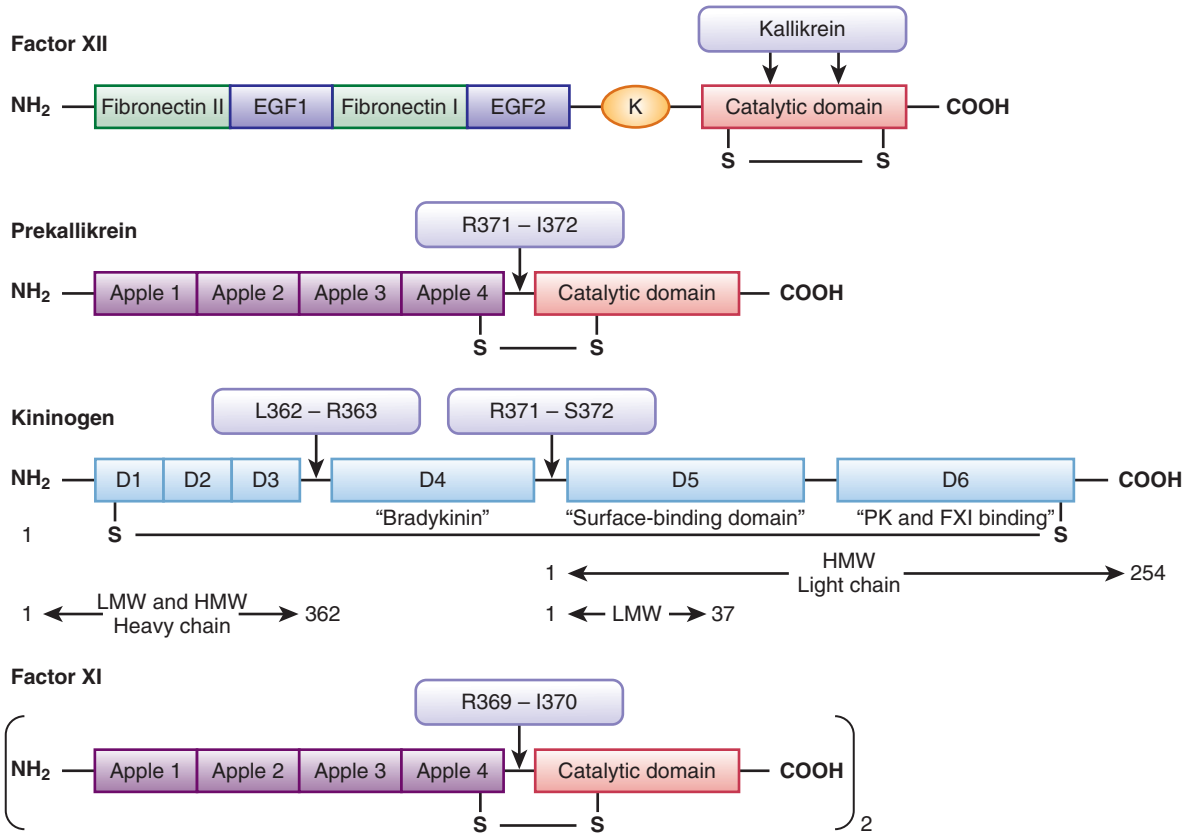

Figure 128-6 SCHEMATIC REPRESENTATION OF THE ACCESSORY PATHWAY (INTRINSIC) PROTEINS. Factor XII, prekallikrein, kininogen, and factor XI are shown with their various domains depicted. Cleavage sites for activation are identified with an *arrow,* and with the specific amino acid residues of the site shown. Key interchain disulfide bonds (S-S) are included. For the kininogens, *horizontal arrows* indicate the amino acid residues defining heavy and light chain regions of the activated forms of the cofactors. Factor XI is illustrated as a monomer. *EGF,* Epidermal growth factor; *HMW,* high molecular weight; *LMW,* low molecular weight.

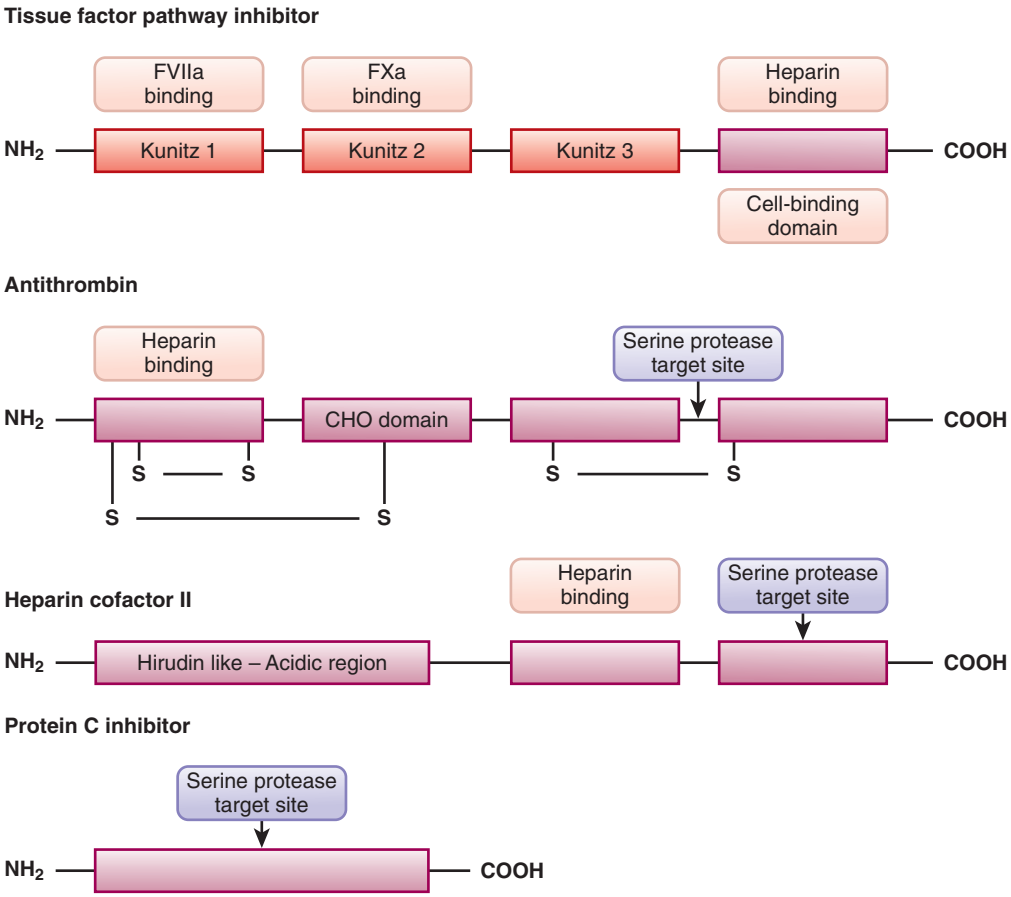

Figure 128-7 SCHEMATIC REPRESENTATION OF SEVERAL PROTEINASE INHIBITORS. Tissue factor pathway inhibitor (TFPI) contains three Kunitz domains. TFPI inhibits the serine proteases factor VIIa (FVIIa) and factor Xa (FXa), shutting down the extrinsic pathway of coagulation. Kunitz 1 domain binds factor VIIa, and Kunitz 2 domain binds factor Xa. The COOH-terminus of TFPI contains a basic region, the cell-binding domain, which binds to heparin. Antithrombin (AT) contains two intrachain disulfide bonds (-S-S-) in its NH_2-terminus and one in its COOH-terminus with a carbohydrate-rich domain (CHO) in between. The region of interaction between the active sites of target proteases and AT is illustrated (reactive center loop). Heparin binding occurs in the NH_2-terminus and enhances the rate of inhibition of serine proteases. Heparin cofactor II (HCII) inhibits thrombin. Structurally, the inhibitor contains an NH_2-terminus hirudin-like region, a heparin or dermatan sulfate binding region, and a reactive center loop. The reactive site is shown at Leu^{444}. Protein C inhibitor (PCI) is a serine protease inhibitor that inhibits several proteases, including activated protein C (APC), thrombin, and factor Xa. It is also a potent inhibitor of the thrombin–thrombomodulin complex. The reactive bond (Arg^{354}) in the reactive center loop is shown.

Antithrombin also displays antiproliferative and antiinflammatory properties that primarily derive from its ability to inhibit thrombin. In addition, latent or cleaved forms of antithrombin have antiangiogenic activities.[143]

Tissue Factor Pathway Inhibitor

Tissue factor pathway inhibitor, formerly called extrinsic pathway inhibitor or lipoprotein-associated coagulation inhibitor, is a multivalent Kunitz-type plasma proteinase inhibitor. It circulates in plasma as a heterogeneous collection of partially proteolyzed forms[144-147] (see Table 128-1 and Fig. 128-7). Up to 90% of circulating TFPI is found associated with lipoproteins, primarily low-density lipoprotein.[144,148,149] Parenteral TFPI is cleared from the circulation mainly by the liver and has an unusually short half-life (minutes) compared with other proteinase inhibitors.

Many reviews of TFPI have been published.[150-160] The importance of TFPI in blood coagulation is best illustrated through transgenic mice with complete TFPI deficiency; the deficiency is embryonic lethal.[154] However, this lethality in mice can be rescued by heterozygous or homozygous factor VII deficiency.[161] This implies that diminishing the level of factor VII lessens the need for TFPI-mediated inhibition of the factor VIIa–tissue factor coagulation pathway during embryogenesis.[161] Similarly, the combination of low normal TFPI with factor V Leiden is lethal.[162,163] Mice with combined heterozygous TFPI deficiency and homozygous apolipoprotein E deficiency develop more extensive atherosclerosis burden,[164] raising the possibility that TFPI contributes to protection from atherosclerosis, as well as serving as a regulator of thrombosis.

Tissue factor pathway inhibitor is the principal stoichiometric inhibitor of the extrinsic factor tenase complex (factor VIIa–tissue factor).[165] Effective TFPI inhibition of the factor VIIa–tissue factor complex depends on the presence of factor Xa. Thus, inhibition of the extrinsic factor tenase by TFPI occurs only after significant factor IXa and factor Xa formation. Inhibition by TFPI is achieved by formation of the stable quaternary, by tissue factor–factor VIIa–TFPI–factor Xa complex, and by formation of the factor Xa–TFPI complex directly.

Heparin Cofactor II

Heparin cofactor II is a member of the serpin family (see Fig. 128-7). The plasma concentration of heparin cofactor II is 0.5 to 1.4 μmol/L[166,167] (see Table 128-1). Its plasma half-life is approximately 2.5 days. Similar to antithrombin, heparin cofactor II inhibits thrombin in a reaction that is accelerated more than 1000-fold by heparin.[168] However, unlike antithrombin, the only coagulation enzyme inhibited by heparin cofactor II is thrombin.[169] The rate of thrombin inhibition by heparin cofactor II in the absence or presence of heparin or heparin-like molecules is significantly slower than by antithrombin under similar conditions. Considering that the plasma concentration of heparin cofactor II is 25% to 50% that of antithrombin and that low levels of heparin cofactor II are not strongly associated with thrombosis,[170] the physiologic role of heparin cofactor II as a systemic thrombin inhibitor has been questioned.

In vitro, heparin cofactor II inhibition of thrombin is accelerated by dermatan sulfate proteoglycans synthesized by fibroblasts and vascular smooth muscle cells.[171] Thus, heparin cofactor II may be uniquely suited to regulate extravascular thrombin in areas of vascular endothelium disruption in which heparin cofactor II would be exclusively stimulated by dermatan sulfate in the subendothelium. In addition, heparin cofactor II may participate in regulation of acute inflammation and wound healing by harboring a peptide chemotactic for neutrophils and monocytes that is released by leukocyte proteolysis.[172]

Heparin cofactor II may also have a role in protection from thrombosis during pregnancy. Increased levels of dermatan sulfate in the maternal and fetal circulation[173] along with increased levels of heparin cofactor II in pregnant women have been reported.[174,175] Low levels of thrombin–heparin cofactor II complexes are detected in normal plasma samples; elevated levels were detected in patients with DIC.[176] Although inherited deficiency of heparin cofactor II has been associated with thrombosis, this is not always the case.[177-179]

Protein C Inhibitor

Protein C inhibitor is a member of the serine proteinase inhibitor family and is also known as plasminogen activator inhibitor-3 (PAI-3). It circulates in blood at a concentration of 5 μg/mL[180,181] (see Table 128-1 and Fig. 128-7) and is cleared from the circulation with a half-life of 1 day. When in complex with a target (e.g., APC), it is cleared from circulation with a $t_{1/2}$ of 20 minutes.[182]

Protein C inhibitor is considered a nonspecific inhibitor in that its targets range from procoagulant (serine proteinases), anticoagulant, and fibrinolytic enzymes to plasma and tissue kallikreins, the sperm protease acrosin, and prostate-specific antigen.[183,184] The major target of protein C inhibitor, as its name suggests, appears to be APC.[182,185,186] Protein C inhibitor has been shown to regulate TAFI activation by inhibiting the thrombin–thrombomodulin complex.[187] Its importance as a dual regulator of coagulation and fibrinolysis remains unresolved.[188,189] Other targets for protein C inhibitor include human plasma kallikrein,[190] factor XIa,[190] factor Xa, and thrombin. Because there are no documented patients with a deficiency to date, the actual function of protein C inhibitor in vivo has yet to be elucidated.

α_2-Macroglobulin

α_2-Macroglobulin is a nonspecific proteinase inhibitor that targets a broad spectrum of protease substrates. It is present in human plasma at concentrations ranging from 2 to 4 μmol/L (2-3 mg/mL). α_2-Macroglobulin can also be found at higher concentrations in extravascular fluids.[191] This protease inhibitor can be produced in a variety of cells, including hepatocytes, fibroblasts, and macrophages.[192,193] Human α_2-macroglobulin circulates in plasma as a tetramer.[191-198] α_2-macroglobulin has a unique mechanism of action, which accounts for its broad specificity. The initial step involves the "bait region" of α_2-macroglobulin.[199] After proteolysis in this bait region, α_2-macroglobulin undergoes conformational changes that trap the proteinase inside the molecule.[199] Consequently, α_2-macroglobulin inhibits a broad range of proteinases. It is distinctive in its capacity to inhibit members from each of four mechanistic classes of proteinases (serine, cysteine, and aspartic proteinases and metalloproteinases). α_2-Macroglobulin functions as a secondary inhibitor of serine proteinases in plasma by inhibiting thrombin, kallikrein, and plasmin.[200,201] It may also be important in preventing thromboembolic events when there is a congenital deficiency of antithrombin or acquired deficiency in sepsis.[202,203] α_2-Macroglobulin also inhibits various growth factors and cytokines, including transforming growth factor- α (TGF-α),[204] interleukin-1β (IL-1β),[205] IL-6,[206] acidic fibroblast growth factor,[207] basic fibroblast growth factor,[207] tumor necrosis factor-α (TNF-α),[208] and IL-2.[209] Polymorphisms identified in α_2-macroglobulin have been thought to play a role in Alzheimer disease.[210-212] Overall, the biologic role of α_2-macroglobulin in vivo is still being elucidated.

Reduced levels of α_2-macroglobulin in humans have been observed in individuals with chronic obstructive lung disease[213] and metastatic cancer.[214] Complete deficiency has not been reported, suggesting that absence of α_2-macroglobulin is incompatible with survival. Inactivation of the α_2-macroglobulin gene in mice has no obvious phenotype, but the mice are resistant to endotoxin challenge.[215] It has been suggested that α_2-macroglobulin serves as a neutralizer of TGF-α and an inducer of nitric oxide synthesis in mice.[216]

Endothelium

Blood cells and the vasculature are crucial to normal hemostasis. Multiple processes involving components of the vessel wall, circulating platelets, and plasma protein moieties interact to maintain blood fluidity. These must be precisely choreographed to allow the vasculature to perform its myriad complex physiologic activities (Fig. 128-8). The endothelium, the thin layer of cells that lines the interior of blood and lymphatic vessels, plays a key role because of its strategic interface among organs, tissues, and circulating blood. The cells that form the endothelium are called *endothelial cells,* those in direct contact with blood are called *vascular endothelial cells,* and those in direct contact with lymph are known as *lymphatic endothelial cells.* Vascular endothelial cells line the entire circulatory system (from the heart to the capillaries).

The endothelium varies in morphology and physiologic function in different parts of the vasculature. This complex cellular network not only provides a structural barrier to contain flowing blood but also regulates blood pressure; vascular tone; permeability; and processes involving other cells such as smooth muscle cells, leukocytes, and platelets, and deposits an intricate basement membrane and extracellular matrix.[217] In addition, the endothelium is involved in inflammatory and immune responses and angiogenesis.[218] Defects in vascular endothelium function, therefore, have profound physiologic implications. Excessive bleeding can result from structural abnormalities of the endothelial cell layer or supporting matrix. Impaired expression or secretion of PAI-1 by the endothelium likewise promote bleeding through increased fibrinolytic activity.[219] Conversely, endothelial cells are also involved in mediating processes that promote atherosclerotic plaque formation and thrombotic pathologies.[220]

The early work of Ware and Seegers[221] identified the phospholipid requirements for coagulation. The biologic elements contributing to the phospholipid include damaged vascular tissue activated platelets and inflammatory cells. The contributions of the membrane to the formation and expression of procoagulant complexes are essential. However, the nature of the membranes that support procoagulant reactions is poorly understood. Mechanically damaged cells can provide the anionic membrane bilayer inner leaflet phospholipids, which can support general procoagulant complex formation; however, more subtle cellular activation events also generate selective complex forming sites on intact cells. Activated platelet membranes express individual binding sites for the factor IXa–factor VIIIa and factor Xa–factor Va complexes. Hemorrhagic pathology is therefore associated with thrombocytopenia and is also displayed in a rare disease, Scott syndrome, which appears to result from the improper

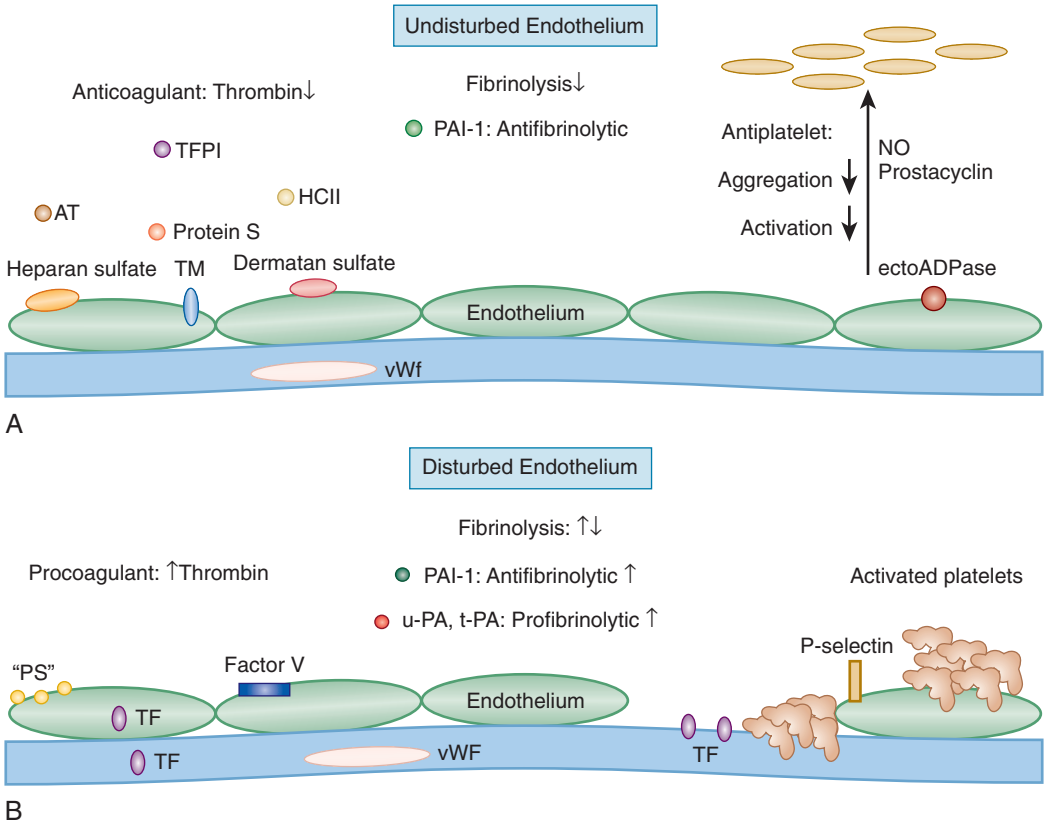

Figure 128-8 SCHEMATIC OF THE CHANGES THAT OCCUR TO THE ENDOTHELIUM UPON INJURY. Under normal conditions in the absence of injury or chemical stimulus **(A),** *the undisturbed endothelium* actively down regulates thrombin generation through production of tissue factor pathway inhibitor (TFPI), antithrombin (AT), protein S, heparan sulfate, thrombomodulin (TM), and dermatan sulfate. The undisturbed endothelium is also antifibrinolytic and secretes plasminogen activator inhibitor-1 (PAI-1). In the absence of a stimulus, the endothelium likewise prevents platelet activation, secretion, and aggregation through production of nitric oxide (NO), prostacyclin, and the membrane-associated protein ectoADPase. When the *endothelium is disturbed* **(B),** the endothelium becomes procoagulant and accelerates thrombin formation by exposing or expressing anionic phospholipid ("PS"), tissue factor (TF), and factor V. The fibrinolytic response is modulated by the release of both antifibrinolytic and profibrinolytic molecules. Urokinase plasminogen activator (u-PA) and tissue plasminogen activator (t-PA) are profibrinolytic and serve to activate plasminogen; PAI-1 inhibits both enzymes and is antifibrinolytic. Platelet activation, secretion, and aggregation are also promoted under conditions in which the endothelium is disrupted. von Willebrand factor (vWF) in the subendothelial matrix is exposed, allowing platelets to attach to the surface of the vessel. P-selectin likewise promotes platelet attachment.

presentation of these platelet binding sites.[222] Binding sites have also been reported on a number of peripheral blood cells, especially activated monocytes. The vascular endothelium itself can provide binding sites after stimulation by cytokine growth factors.[223] The endothelium also provides the anticoagulant thrombomodulin, TFPI and heparan sulfate. The endothelial cell protein C receptor provides cell-specific binding sites for both protein C and APC.[44,224] Endothelial cell protein C receptor is down-regulated by TNF-α.[44] Monocytes appear to express specific binding sites for APC that are distinct from the endothelial cell protein C receptor.[225] The cell-expressed binding sites may be important in the antiinflammatory properties of APC.[46]

A further consequence of damage to the endothelium is the release of pathologic quantities of vWF, which promote platelet aggregation and adhesion to the subendothelium and thus the formation of potentially fatal thrombi. Endothelial dysfunction is also linked with hypertension, diabetes, obesity, and hyperlipidemia.

Platelets

Platelets, or thrombocytes, are vital to procoagulant events and contribute to the fibrinolytic process as well. They are small, irregularly shaped clear cell fragments, which are derived from megakaryocytes. The average lifespan of a platelet is approximately 5 to 9 days. Platelets are at the balance of bleeding or clotting events: when platelet numbers are low (thrombocytopenia), excessive bleeding can occur, and when platelet numbers are high (thrombocytosis), thrombosis can occur. Disorders that reduce the number of platelets but typically cause thrombosis instead of bleeding are heparin-induced thrombocytopenia and thrombotic thrombocytopenic purpura.

Similar to the endothelium, the undisturbed platelet presents a nonthrombogenic surface. Important components of platelet physiology are surface adhesion protein complexes and the platelet secretory granules: α-granules, lysosomes, and dense granules. Contents of the α-granules include procoagulant and adhesive proteins such as fibrinogen, fibronectin, thrombospondin, vWF, P-selectin, HMWK, platelet factor 4, osteonectin, factor V,[59] and factor XI.[226] Other α-granule contents, α_1-antitrypsin, protein S, TFPI, and platelet inhibitor of factor XI are involved in anticoagulant activities.[227-229] The α-granule also contains proteins that meditate both pro- and antifibrinolytic processes. These proteins include plasminogen, α_2-antiplasmin, factor XIII, and PAI-1.[230-234] In the unstimulated platelet, the granule contents remain internalized and anionic phospholipid is sequestered in the inner leaflet of the plasma membrane. Prostaglandin I2

(prostacyclin) and nitric oxide released from endothelial cells, the presence of CD39, and the inability of normal plasma vWF to bind spontaneously to the platelet surface are the inhibitory mechanisms that keep platelets unactivated.[235]

When the vascular system is perturbed, platelet plug formation occurs in stages. During the first stage, platelets adhere and are activated by exposure to collagen and vWF and other matrix components (Fig. 128-9). The cytoskeleton spreads and platelet-fibrinogen aggregates are formed and the contents of the granules are secreted.[236-238] The activated platelets adhere to each other, endothelial cells, leukocytes, and components of the subendothelial matrix.[239] The phosphatidyl serine (PS) rich internal face of cell membranes are exposed and present a highly procoagulant surface to the circulation.[240] In addition, activated platelets express specific receptors or binding sites for the assembly of the procoagulant multiprotein complexes (Fig. 128-10). There are approximately 3000 factor Va binding sites on the activated platelet membrane.[241] Factor Va forms part of the receptor for factor Xa. Factor Xa is also reported to bind to effector cell protease receptor-1 (EPR-1) molecules expressed on activated platelets.[241-244]

In the extension phase of platelet plug formation, where activated platelets accumulate on top of the initial monolayer of platelets bound to collagen, the presence of receptors on the platelet surface allows agonists such as thrombin, adenosine diphosphate, and thromboxane A_2 to recruit additional circulating platelets into the growing hemostatic plug (see Fig. 128-10). Subsequently, during the platelet plug formation perpetuation phase, close contacts between platelets promote the growth and stabilization of the hemostatic plug, in part through contact-dependent signaling mechanisms.[235]

Clot Proteins

A central event in blood coagulation is the conversion of soluble fibrinogen (factor I) to insoluble fibrin (see Fig. 128-1; for reviews, see References 245 and 246). Fibrinogen functions in hemostasis to stem blood loss. It serves as a molecular bridge to support interplatelet aggregation, and it is the precursor of fibrin, which is the main component of the protein scaffolding of the forming hemostatic plug.

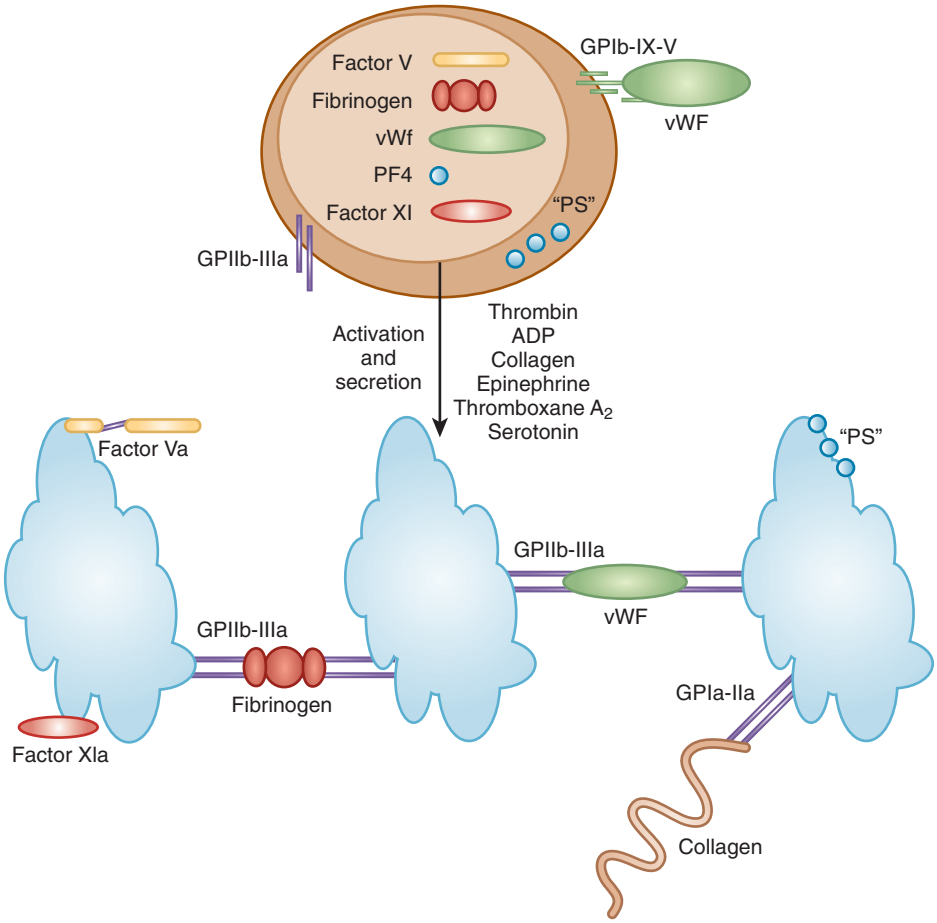

Figure 128-9 SCHEMATIC OF PLATELET ACTIVATION, SECRETION, AND AGGREGATION. Platelets have multiple functions in hemostasis. They serve as reservoirs of factor V, fibrinogen, von Willebrand factor (vWF), platelet factor 4 (PF4), and factor XI. Platelets also contribute a significant portion of the anionic phospholipid ("PS") necessary for membrane-dependent complex formation and function. In the unstimulated state, proteins and other molecules are sequestered in the platelet granules. Anionic phospholipid is found only in the inner leaflet of the platelet membrane and is not exposed to flowing blood. The glycoprotein (GP) Ib-IX-V complex, which recognizes vWF, is an active receptor, but the GPIIb-IIIa receptor, which recognizes a variety of molecules, including fibrinogen and vWF, is not active. The GP Ib-IX-V receptor likely allows unstimulated platelets to attach to exposed subendothelial vWF, thereby promoting procoagulant events before platelet activation. Upon activation by a variety of agonists, platelets secrete granule contents, become activated and bind factor V/Va and factor XI/XIa, and expose anionic phospholipid. The GPIIb-IIIa receptor serves to link platelets to each other and the vessel wall. Collagen receptors, such as GPIa-IIa, promote both platelet activation and aggregation. *ADP,* Adenosine diphosphate.

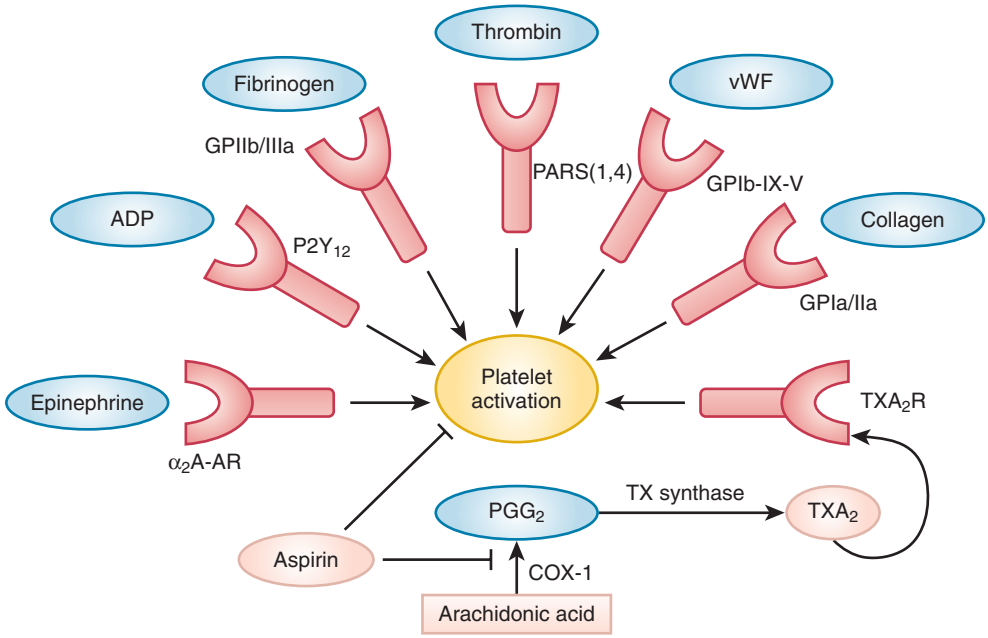

Figure 128-10 SELECTED PLATELET RECEPTOR TARGETS AND THEIR RESPECTIVE INHIBITORY AGENTS. When a platelet encounters a break in the endothelium, it encounters molecules that trigger its activation, such as collagen, thromboxane A_2 (TXA_2), adenosine diphosphate (ADP), and thrombin. The ability of platelets to adhere, aggregate, respond to agonists, aid in coagulation, and bind fibrin are all processes mediated by the plasma membrane glycoproteins of the platelet. The platelet glycoprotein (GP) IbIX-V constitutes the receptor for von Willebrand factor (vWF). GPIa/IIa mediates platelet–collagen interactions. GPIIb/IIIa is a receptor for fibrinogen. $P2Y_{12}$ is a chemoreceptor for ADP. The α_2A-adrenergic receptor (α_2A-AR) is expressed on platelets and binds the naturally occurring ligand epinephrine. Cyclooxygenase-1 (COX-1) is responsible for the formation of prostaglandins and thromboxane. COX-1 converts arachidonic acid to prostaglandin G_2 (PGG_2). Aspirin irreversibly inhibits COX-1.

Platelet aggregation critically depends on fibrinogen binding to activated platelets via the platelet fibrinogen receptor GPIIb/IIIa as well as fibrin adhesion (see Fig. 128-10). Fibrinogen/fibrin also regulates thrombin activity by interactions that include the proteolytic cleavage by thrombin of fibrinopeptides[247,248] to form a fibrin clot and thrombin exosite binding to fibrin, which potentially limits the diffusion of thrombin, thereby regulating clot propagation. The structure, stability, and duration of insoluble fibrin are controlled by an interplay between fibrin formation and fibrinolysis, which includes other molecular and cellular components.

The description of fibrinogen activation and fibrin assembly has been based on studies using citrated plasmas or purified proteins. The three main players in fibrinogen to fibrin conversion are the enzyme thrombin, the substrates fibrinogen and the cross-linking tranglutaminase factor XIII. Fibrinogen is composed of six polypeptide chains (two Aα, two Bß, and two γ chains) that form two symmetrical half molecules (three chains each) with the NH_2 termini crosslinked to each other. The outside two domains of fibrinogen are composed of the Bß and γ chains and designated as the D domain. The central domain that contains the NH_2-termini of all the chains is designated as the E domain. From x-ray crystallographic data, fibrinogen has a trinodular structure aligned as D–E–D domains (Fig. 128-11).

The kinetics of fibrinogen cleavage by thrombin results in the hydrolysis of Arg–Gly bonds removing small, polar amino terminal fragments (fibrinopeptides [FPs]) from the NH_2-terminal of the Aα and Bß chains Fig. 128-11.[249,250] Cleavage at the Arg–Gly bond of the Aα chain releases FPA and forms fibrin I. The release of two FPA peptides exposes a site in the E domain that interacts with a site in the D domain to form overlapping fibrils. Subsequent cleavage of the Arg–Gly bond on the Bß-chain releases FPB to form fibrin II, presumably increasing lateral aggregation of the protofibrils.[251]

An important enzyme for the structure and stability of the fibrin clot is the transglutaminase factor XIIIa.[252-254] Its function is to cross-link fibrin and other adhesive proteins, including integrin receptors providing a stable network. Only the Aα chain and the γ chain, which has donor (Gln) and acceptor (Lys) sites, participate in cross-linking of adjacent glutamyl and lysyl residues by factor XIIIa.[251,255-257]

Fibrinogen also is required for competent inflammatory reactions. Fibrinogen is an acute phase reactant whose levels increase during inflammation.[258,259] In these situations, fibrinogen functions as a bridging molecule in cell–cell interactions.[260,261] Fibrin and fibrinogen constitute a matrix that modulates cellular responses in a variety of cell types, including endothelial cells, epithelial cells, leukocytes, platelets, and fibroblasts. Cellular receptors that bind fibrinogen and fibrin include the integrins $\alpha_{IIb}ß_3$, $\alpha_V ß_3$, and $\alpha_5 ß_1$, and the cellular adhesion molecules intercellular adhesion molecule-1 and vascular endothelial cadherin.[262-265]

Fibrin clot based assays have been extensively used in the clinical diagnosis of bleeding disorders. Two in vitro plasma tests, the PT[266,267] and the activated partial thromboplastin time (aPTT),[268] segregate the coagulation process into tissue factor initiated or surface contact processes, respectively. The aPTT, which initiates coagulation by the introduction of a foreign surface, only examines the biologic constituents intrinsic to plasma. This assay is sensitive to isolated or combined deficiencies of factor XII, HMWK, prekallikrein, factor XI, factor VIII, factor IX, factor X, factor V, prothrombin, and fibrinogen. The PT assay is based on initiating coagulation via an extrinsic source of tissue factor (thromboplastin). The PT assay is sensitive to isolated or combined deficiencies of factor VII, factor X, factor V, prothrombin, and fibrinogen. Although these in vitro clotting assays help establish a basis for hemostasis, abnormal test results are not always mirrored by human pathology associated with bleeding or thrombosis.

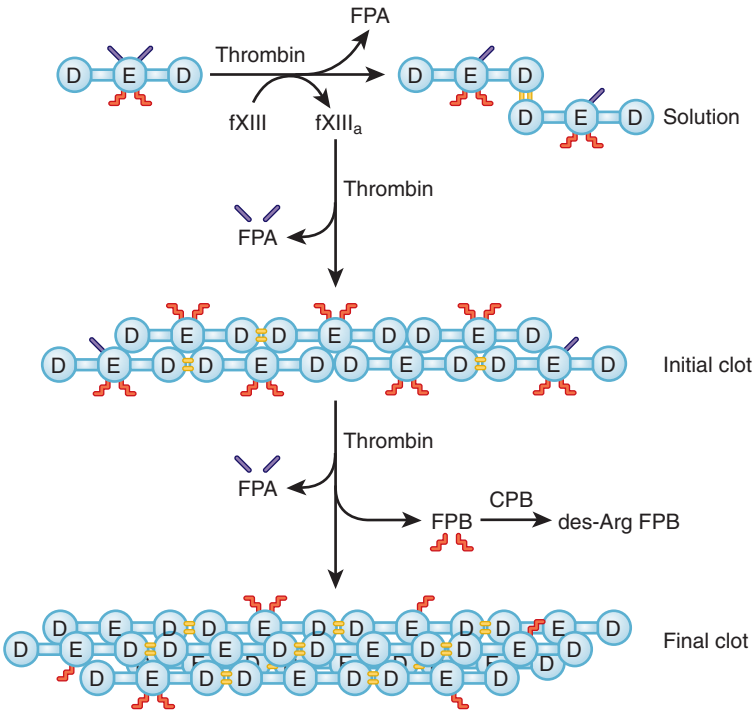

Figure 128-11 SCHEMATIC REPRESENTATION OF WHOLE-BLOOD FIBRIN FORMATION. At the start of clot formation, thrombin simultaneously acts on fibrinogen (D-E-D) and factor XIII (fXIII). A portion (≈40%) of fibrinopeptide A (FPA) is released from fibrinogen, and an initial clot is formed from the complementary overlap of the exposed sites between the E and D domains of adjacent fibrin molecules. Activated factor XIII (fXIIIa) simultaneously cross-links adjacent D domains (D=D). Thus, the initial soluble fibrin clot is composed of fibrinogen, fibrin, and γ-γ dimers with fibrinopeptide B (FPB) still attached. The initial clot is continuously acted on by thrombin, releasing the remaining FPA and some of the FPB to yield a final clot with the majority of FPB still attached. The released FPB is selectively acted on by a carboxypeptidase B–like enzyme (CPB, potentially thrombin activatable fibrinolysis inhibitor a [TAFIa]) which cleaves the carboxyl terminal arginine to produce des-Arg FPB. The significance of this cleavage is still unclear. *(From Brummel KE, Butenas S, Mann KG: An integrated study of fibrinogen during blood coagulation.* J Biol Chem *274(32):22862-72280, 1999, with permission.)*

Fibrinolysis Proteins

Clot formation is integrated with clot dissolution (fibrinolysis). Fibrinolysis, the elimination of blood clots, has two types, primary fibrinolysis and secondary fibrinolysis. Whereas primary fibrinolysis is a normal body process, secondary fibrinolysis is the breakdown of clots due to a medicine, a medical disorder, or some other cause.

The biochemical mechanisms of clot dissolution center on fibrin specific activation of plasminogen to plasmin. The key proteins involved are plasminogen, the plasminogen activators tissue plasminogen activator (t-PA) and urokinase plasminogen activator (u-PA), and the inhibitors (PAI-1, α_2-antiplasmin, and TAFIa). Plasminogen is the inactive precursor of the enzyme plasmin, which is the primary catalyst of fibrin degradation (Fig. 128-12).[269] The process of plasminogen activation can occur through three distinct pathways: (1) the intrinsic activator system (analogous to the contact system of blood coagulation), (2) the extrinsic activators (t-PA and u-PA), and (3) an exogenous activator system involving pharmacologic agents (fibrinolytic drugs). The primary pathway used in vivo appears to be the extrinsic pathway. However, both the intrinsic as well as exogenous activator systems can play important roles in human disease.

t-PA and u-PA, secreted by the endothelium, have unique structures and properties that affect the specificity and rate of plasmin generation (see Fig. 128-12).[270] After being generated, plasmin digests fibrin in a pattern that produces a collection of degradation products, including fragment X; fragment Y; and the core fragments, fragments D and E. The first step in degrading fibrin is the removal of the α chains, thus exposing the coiled coils. As these coils are cleaved, different sized fragments are released.[271] Fibrinogen is represented as a trinodular structure (D-E-D domains) with each E domain and D domain separated by a coiled coil domain. Upon formation of fibrin crosslinks occur between alternating molecules of fibrin at the D domain (D=D). Plasmin degrades fibrin releasing various sized fragments, the smallest of which is the D=D or D-dimer (M_r=180,000). The largest of these fragments is XXD, X=D–E–D, with a mass of 595,000.[272,273] Elevated levels of D-dimer are found in the blood of patients with various thrombotic and thrombolytic disorders.[274] These circulating fragments are cleared by other proteases or by the kidney and liver.

Inhibitors of the Fibrinolytic System

Plasminogen activation in blood is primarily inhibited by PAI-1, which targets u-PA and t-PA. PAI-1 also has a role in tissue remodeling by interfering with vitronectin-dependent processes of cell adhesion and migration.[275] Congenital deficiency of PAI-1 is rare with homozygous individuals displaying abnormal bleeding in response to trauma.[276] Platelets contribute to the fibrinolytic process by binding t-PA and plasminogen and supporting plasmin generation. Increased levels of plasma PAI-1 delay fibrin removal by shortening the functional lifetime of plasminogen activators, thereby shifting hemostasis to a more thrombotic state.[277]

TAFI is a plasma zymogen with homology to procarboxypeptidases A and B (see Fig. 128-12).[55,278-280] Activation of TAFI yields the exopeptidase (TAFIa) with carboxypeptidase B–like substrate specificity. TAFIa catalyzes the removal of basic amino acids (arginine, lysine) from the COOH-termini of polypeptides. The activation of many of the cofactors and zymogens of the coagulation and fibrinolytic cascades results in the generation of functional proteins with COOH-terminus arginine or lysine residues. COOH-terminus lysine residues that appear in fibrin fragments degraded with plasmin have been identified as the major substrates for TAFIa. The physiologic activator of TAFIa is the thrombin–thrombomodulin complex, thus defining TAFIa as a coagulation-dependent activity.[281] Because TAFIa functions as an attenuator of fibrinolysis,[53] an adequate rate of TAFIa generation appears critical for the stabilization of the blood clot. Plasmas with specific deficiencies in the coagulation pathway exhibit reduced rates of thrombin production, decreased levels of TAFIa, and premature clot lysis.[257,282,283]

Fibrinolytic drugs are often given after a myocardial infarct or ischemic stroke to dissolve the fibrin clot blocking the coronary or cerebral artery. Fibrinolytic drugs are also used in massive pulmonary embolism. Antifibrinolytics, such as aminocaproic acid (ε-aminocaproic acid) and tranexamic acid, are used as inhibitors of fibrinolysis.

CONNECTIVITY AND DYNAMICS IN HEMOSTASIS

In the healthy state, the hemostatic system is relatively quiescent with the vascular endothelial cells, the blood, and the extravascular tissue

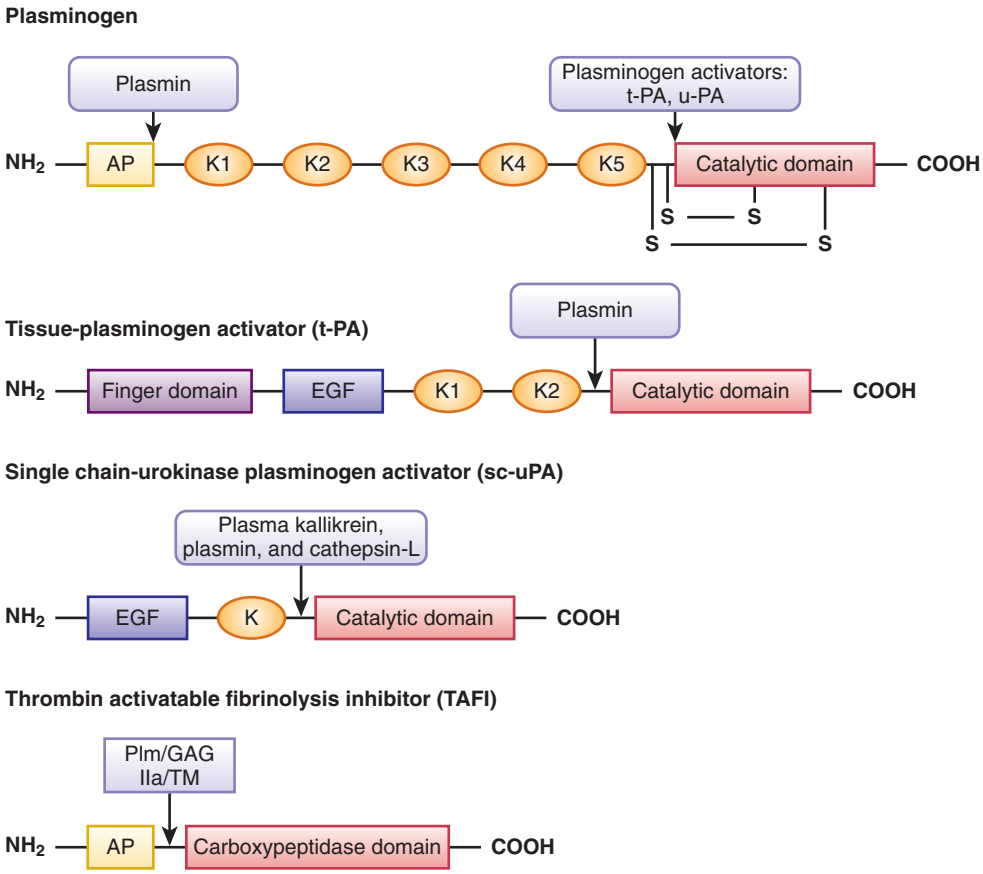

Figure 128-12 SCHEMATIC OF FIBRINOLYTIC PROTEINS. *Plasminogen* is the inactive precursor of the enzyme plasmin, which is the primary catalyst of fibrin degradation. The domain structure of human plasminogen is represented by Kringle domains (K1–K5), a catalytic domain, and the *arrows* indicate the sites of proteolytic cleavage by plasmin, elastase, and plasminogen activators (tissue plasminogen activator [t-PA] and urokinase plasminogen activator [u-PA]). Disulfide bonds are illustrated by S-S. The t-PA molecule is a serine proteinase and consists of an A and B chain. The A chain consists of a fibronectin fingerlike domain, an epidermal growth factor (EGF)–like domain, and two kringle domains. The kringle 2 domain and the finger domain of t-PA are involved in the binding of t-PA to fibrin. The B-chain of t-PA contains the active site catalytic triad. Single-chain t-PA is an efficient plasminogen activator in the presence of fibrin and is converted to the two-chain form by cleavage of the peptide bond between R^{275} and I^{276}. This cleavage is performed primarily by the action of plasmin during fibrinolysis. *Single-chain u-PA* (sc-uPA) is a serine protease and is an ineffective catalyst. Plasmin or plasma kallikrein can hydrolyze the K^{158}-I^{159} peptide bond, converting sc-uPA into the fully active two-chain form (two-chain urokinase-type plasminogen activator). u-PA is composed of an EGF domain (EGF), a single kringle domain, a connecting peptide region, and the serine protease-type catalytic domain. *Thrombin activatable fibrinolysis inhibitor (TAFI):* Activation of TAFI (TAFIa) yields an exopeptidase with carboxypeptidase B–like substrate specificity. TAFIa delays fibrinolysis by cleaving COOH-terminus Arg (R) or Lys (K) residues made available as a consequence of partial plasmin digestion of the fibrin clot. Removing these residues attenuates the self-amplifying mechanism of fibrin-based plasmin formation wherein partial plasmin proteolysis of fibrin increases the number of binding sites (COOH-terminal lysines) available for efficient plasminogen activation. TAFI contains an activation peptide region and a carboxypeptidase domain. It is activated by the thrombin–thrombomodulin complexes (IIa.TM) and plasmin–glycosaminoglycan complexes (Plm/GAG) by hydrolysis of the R^{92}–A^{93} bond.

functioning to maintain fluidity. Blood platelets remain in a quiescent state because of the endothelial cell lining of the blood vessel being an active anticoagulant that secretes small molecules and enzymes. The endothelium also provides constituent anticoagulant proteins, which inhibit the blood coagulation system. These vascular anticoagulant systems are both passive and dynamic in nature and function in cooperation with plasma components. The blood supplies pro- and anticoagulant proteins in the plasma and platelets, which contribute to the coagulation reaction. If the endothelium becomes damaged, the pro- and anticoagulant levels become imbalanced, and cells that should remain in the blood can leak through blood vessels into adjacent body tissue, which triggers a response. The dimensions of the response are relevant to the injury. The extravascular compartment and blood interact to rapidly produce a vigorous local coagulation response, which attenuates blood loss and initiates the vascular repair process in four phases: initiation, propagation, termination, and elimination and fibrinolysis.[284-286]

Initiation

If vascular injury occurs, a measured response is triggered in that the extent of damage regulates platelet and fibrin deposition. Activated platelets provide the membrane surfaces upon which coagulation enzymes can be anchored, assembled, and expressed. Therefore, the activated platelet membrane, provides both an initiating and limiting

component to the extent of a coagulation reaction.[287] More vascular damage produces more anchored activated platelets, and more membrane allows the assembly of more coagulation enzymes, which ultimately results in increased fibrin formation.

When the vascular system is perturbed, the initial stages of the hemostatic response are triggered. The initial principal player is the extrinsic tenase complex (tissue factor–factor VIIa), which is composed of a cell membrane; tissue factor exposed by vascular damage or cytokine stimulation; Ca^{2+}; and the serine protease plasma factor VIIa, which is already present in its active form at 1% to 2% of the factor VII zymogen concentration[53,288] (Fig. 128-13). Before binding to tissue factor, the plasma serine protease factor VIIa is essentially inert from the catalytic

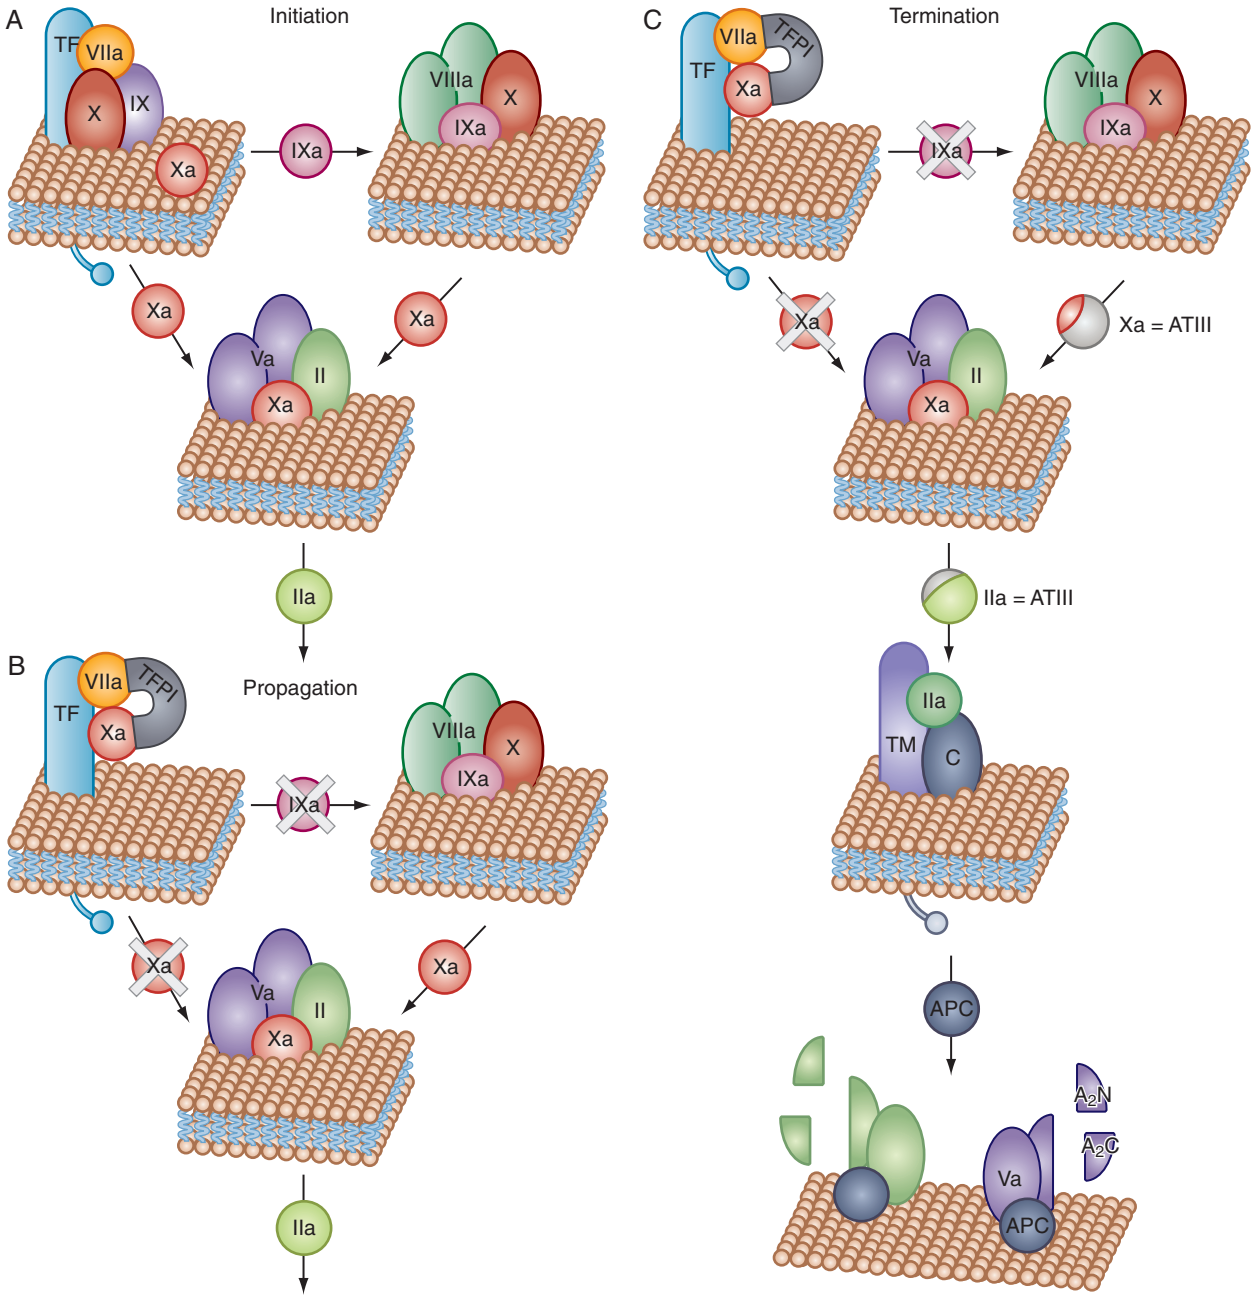

Figure 128-13 REGULATION OF THE DYNAMIC PROCOAGULANT RESPONSE. Initiation **(A)** propagation **(B)** and termination **(C)** of thrombin generation and the procoagulant response are illustrated. Four vitamin K–dependent complexes are shown: extrinsic tenase, intrinsic tenase, prothrombinase, and protein Case. The procoagulant response is regulated by the stoichiometric inhibitors antithrombin (AT) and tissue factor pathway inhibitor (TFPI). AT inhibits thrombin, factor Xa, and factor IXa that are free in solution. TFPI inhibits both factor Xa and the factor VIIa–tissue factor (TF)–factor Xa complex. Activated protein C (APC) generated from the protein Case complex (thrombomodulin [TM]–thrombin [IIa]) inactivates FVa and FVIIIa by proteolysis of their heavy chains. Low levels of thrombin are required to initiate clot formation (initiation phase) and trigger the coagulation cascade response (propagation phase). The enzymes, cofactors, and inhibitors act together to generate a hemostatic response that can be divided into an initiation phase and a propagation and termination phase. During the initiation phase, factors X and IX are converted to their respective serine proteases factor Xa and factor IXa; low levels of thrombin are subsequently generated by factor Xa. This thrombin then can activate platelets and the procofactors factors V and VIII, which stimulate further thrombin generation during the propagation phase. Thrombin generation is attenuated by shutting down the initiation phase by means of the stoichiometric inhibitor of the extrinsic tenase complex, TFPI, followed by AT, which directly inhibits thrombin and factors Xa and IXa. *(From Mann KG:* Coagulation explosion. *Vermont Business Graphics, Burlington, Vermont, 1997, with permission.)*

perspective and thus impervious to the abundant protease inhibitors in plasma.[289] Factor VII also competes with factor VIIa for tissue factor binding, thus serving as a negative regulator that buffers the overall reaction.[290,291] Factor VII activating protease (FSAP) has also been shown to activate factor VII in the absence of tissue factor.[292-294] The physiologic function of FSAP still is unclear but most recently has been suggested to be involved in inflammation (for a review, see Reference 295). The extrinsic tenase complex (tissue factor–factor VIIa) activates low levels of the zymogens factor X and factor IX to their respective serine protease enzymes factor Xa (≈10 pM) and factor IXa (≈1 pM).[296,297] Factor X is the more efficient and abundant substrate.[298,299]

The extrinsic tenase complex is under tight supervision by TFPI, which can bind both the complex and the product factor Xa (see Fig. 128-13).[300,301] TFPI, present in low abundance in blood, is released from the vasculature by heparin.[302] If the initiating procoagulant stimulus is sufficient to overcome the level of this anticoagulant response, a threshold is exceeded and downstream complexes can be formed.

The limited amounts of factor Xa that escapes inhibition by TFPI and antithrombin bind to available membrane sites and can activate tiny amounts of prothrombin to thrombin (see Fig. 128-13).[303] The time period in which factor Xa directly generates picomolar amounts of thrombin[304] is referred to as the *initiation phase* of blood coagulation (Fig. 128-14). During the initiation phase, circulating blood cells and procoagulant proteins are activated,[305] the procoagulant elements necessary for the full procoagulant response are generated, and a

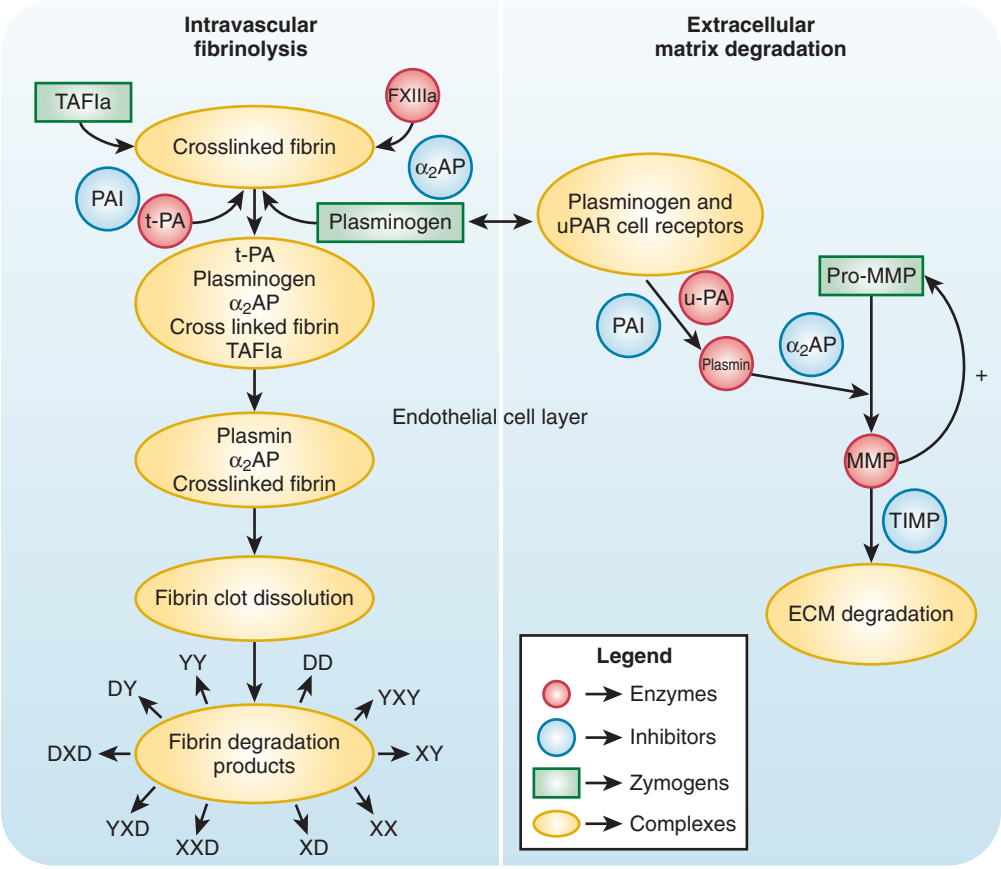

Figure 128-14 SCHEMATIC OF THE DYNAMIC INTERACTION BETWEEN THE PROTEINS AND INHIBITORS OF FIBRINOLYSIS. Cross-linked fibrin formation is integrated with fibrin clot dissolution and degradation of its products. Two pathways are shown, intravascular fibrinolysis and extracellular matrix, separated by an endothelial cell layer. The enzymes *(red circles),* inhibitors *(blue circles),* zymogens *(green boxes),* and complexes *(large yellow ovals)* are illustrated in a simplified form to show this multicomponent process. The key proteins of the fibrinolytic system *(left panel)* are plasminogen, the plasminogen activator tissue type plasminogen activator (t-PA), plasminogen activator inhibitors (PAI), α_2-antiplasmin (α_2-AP) and thrombin activatable fibrinolysis inhibitor (TAFI), and the transglutaminase activated factor XIII (FXIIIa). t-PA and plasminogen both bind to the fibrin surface, crosslinked by FXIIIa, where t-PA is an effective catalyst of plasminogen conversion to plasmin. Initially, plasmin proteolysis of fibrin generates new COOH terminus lysine residues, which function as higher affinity binding sites for plasminogen, setting up an amplifying loop of plasminogen activation. Formation of activated TAFIa results in removal of the plasmin-generated COOH-terminus lysine residues, thus suppressing the rate of fibrin lysis. Opposing these events are antifibrinolytic mechanisms. Soluble and cross-linked α_2-AP complexes with plasmin rendering it inactive. PAI rapidly reacts with t-PA thus reducing the concentration of the plasminogen activator. Fibrin degradation occurs by plasmin cleavage at the D-E-D domains of fibrin polymers to yield a variety of polymers as illustrated (for a definition of the D-E-D domain, see Fig. 128-11). Plasminogen can cross the endothelial cell layer and become converted to plasmin by the urokinase type plasminogen activator (u-PA) *(right panel).* Plasmin can convert latent matrix metalloproteinases (pro-MMP) to their active form (MMP). MMPs themselves can act in a positive feedback mechanism to convert pro-MMP to more MMP, which ultimately degrade the extracellular matrix. Plasmin-mediated effects are inhibited by PAI and α_2-AP. MMP-mediated effects are inhibited by tissue inhibitors of metalloproteinases (TIMP).

preliminary fibrin network is formed.[306] Although this process is inefficient, this initial thrombin is essential for the acceleration of the process by serving as the activator of platelets through cleavage of protease activated receptors (PAR1 and PAR4)[307] and the activation of the procofactors factor V and factor VIII.[129] Thrombin also activates factor XI to factor XIa[130], initiating the accessory pathway that enhances factor IX activation.[308]

In analyses of tissue factor–induced activation of the coagulation process in whole blood, the initial period of thrombin generation (based on levels of thrombin–antithrombin complexes) illustrates that most catalyst formation occurs before fibrin clot formation (see Fig. 128-14).[305] The small amount of thrombin that is generated during the initiation phase is from the extrinsic factor tenase and is able to activate platelets,[309] factor XIII,[310] factor V,[311] and factor VIII[312] and release some fibrinopeptide A and fibrinopeptide B[263] from fibrinogen to form fibrin. Less than 2% of the final thrombin produced is required to achieve the activation of these catalysts produced in blood to form the initial clot. However, activation of the catalysts is essential to generate the bulk of thrombin (≈95%) that is formed during the propagation phase of the reaction. The aggregated platelets and fibrin resulting from thrombin formation are the principal components of the initial vascular plug formation.

After the cofactor factor VIIIa is formed, it combines on activated platelets with the serine protease factor IXa that was generated by the tissue factor–factor VIIa complex to form the intrinsic tenase complex (see Fig. 128-13). This complex is the major activator of factor X; it is 50-fold more efficient than factor VIIa–tissue factor in catalyzing factor X activation.[299,313] The extrinsic tenase complex is under the control of TFPI.[314,315] In the absence of factor VIII (hemophilia A) or factor IX (hemophilia B), the intrinsic tenase complex cannot be assembled; thus, no amplification of factor Xa generation occurs. This is the principal defect observed in hemophilia[316,317]: initial production of factor Xa by the tissue factor–factor VIIa complex is inadequate to efficiently stem blood flow.

Factor Xa combines with factor Va on the activated platelet membrane surfaces at specific receptor sites to form the prothrombinase complex; the principal generator of thrombin (see Fig. 128-13).[318,319] This process serves as a major amplification loop of blood coagulation. The factor IXa and factor Xa constituent of prothrombinase and the intrinsic tenase complex are protected from inhibition by antithrombin and other plasma inhibitors when in the complexed form.

Propagation

When a sufficient stimulus is provided to overcome the antagonist–inhibitor threshold, the accumulating mass of activated platelets will support increasing intrinsic tenase and prothrombinase complex formation on their surfaces through specific platelet receptors, and the local inhibitor concentrations are overwhelmed (see Fig. 128-13). These platelet-bound catalysts execute the propagation phase of the reaction, during which massive amounts of thrombin are produced.[320] This phase of thrombin generation continues, independent of the initially presented tissue factor, as long as there is a continuous supply of blood to deliver new plasma procoagulant reactants, platelets, and fibrinogen to the site of perforation in the vascular endothelium.

Important to the formation of the prothrombinase complex is the generation of factor Xa. Factor Xa is a unique regulatory enzyme in that it is formed through both the intrinsic tenase and the extrinsic tenase complexes. Under normal conditions, the concentration of factor Xa is the rate-limiting component of the prothrombinase complex. The other components of the complex, platelets (membrane surface binding sites), and the cofactor (factor Va) are activated rapidly to produce a surplus that is ready for action.[318] The coagulation mechanism can become sensitive to factor V or platelets when confronted with congenital deficiencies, thrombocytopenia, platelet pathology, or pharmacologic interventions.[321,322]

The initial factor Xa is generated via the tissue factor–factor VIIa complex during the initiation phase. Additional factor Xa is then generated by the intrinsic tenase complex (factor IXa–factor VIIIa–membrane–Ca^{2+}). Initially, the concentration of the factor VIIa–tissue factor complex is higher than the concentration of the factor VIIIa–factor IXa complex, which requires activation and assembly. As time progresses, the contribution of the intrinsic tenase complex to factor Xa generation exceeds that of the extrinsic tenase.[323] The intrinsic tenase complex is kinetically more efficient and activates factor X at a 50- to 100-fold higher rate than the extrinsic tenase complex.[299,324,325] The burst of factor Xa that is generated overcomes the levels of factor Xa inhibitors, such as TFPI, and achieves maximal prothrombinase activity and propagation of the procoagulant response.[162,314] The bulk of thrombin (≈95%) is formed during the propagation phase after fibrin clot formation.[305,326] Without the intrinsic tenase complex being formed, as occurs in hemophilia A or B, factor Xa is not generated in levels sufficient to produce the propagation phase of thrombin generation.[316,327]

Because the presentation of a clot in a low tissue factor model depends on the generation of 10 to 30 nM thrombin,[305,326] at high tissue factor concentrations, tissue factor–factor VIIa generate factor Xa rapidly and masks the contribution of the factor VIIIa–factor IXa complex in clot end point assays. This is the case for the PT[266,267] in which the concentration of the initiator, thromboplastin (tissue factor and phospholipid), is chosen to produce a clot time of 11 to 15 seconds. This corresponds to a tissue factor concentration over 20 nM. In our whole-blood studies, a concentration of 5 pM tissue factor is used, which produces a clot time in the range of 5 minutes.[305,326] Therefore, in hemophilia A, the PT does not reflect a change in clot time in this well-established hemorrhagic disease. The major defect occurs after clot time, during the propagation phase of thrombin generation, which is dramatically decreased.[316,320,328]

Termination

When blood flow has ceased because of the formation of a fibrin–platelet "dam," the overwhelming concentration of inhibitors present in blood, including TFPI and antithrombin, heparin cofactor II, α_2-macroglobulin, α_1-antitrypsin, and protein C inhibitor, can "catch up" and inhibit the various reactants as they dissociate from their respective complexes (see Fig. 128-13).[150,314,329-331]

In the intact vasculature surrounding the growing thrombus, procoagulant enzymes and cofactors escaping the wound site are rapidly quenched under normal circumstances by the stoichiometric and dynamic inhibitory systems of blood in cooperation with elements of the vascular endothelium. The free serine proteases (thrombin, factor IXa, and factor Xa) of the coagulation system in the plasma environment are rapidly inhibited by the surplus of antithrombin molecules. The reaction is accelerated by the interaction of antithrombin with heparan sulfate proteoglycans presented constitutively on the surface of vascular endothelial cells.[332]

Any thrombin escaping from the wound site may bind resident thrombomodulin molecules constitutively expressed by vascular endothelial cells. Thrombomodulin-bound thrombin is converted from a procoagulant enzyme to an anticoagulant enzyme.[333,334] The thrombin–thrombomodulin complex (protein Case) activates protein C, which in turn downregulates the intrinsic factor tenase and prothrombinase procoagulants by cleaving factor VIIIa and factor Va, respectively. The rates of APC inactivation of factors Va and VIIIa are enhanced by protein S. TAFI is also activated by protein Case and serves to delay clot lysis (for reviews, see Reference 53 and 335). Cleavage of factor Va by APC and inhibition of thrombin generation also reduces thrombin–thrombomodulin–mediated TAFI activation.[336]

When operating properly, this system of blood leakage attenuation displays the appropriate level of procoagulant required to obstruct blood loss but is precluded from systemic activation of the coagulation system. The converse to hemostasis occurs when the damaging insult for the vasculature is internal to the vessel lumen.[337]

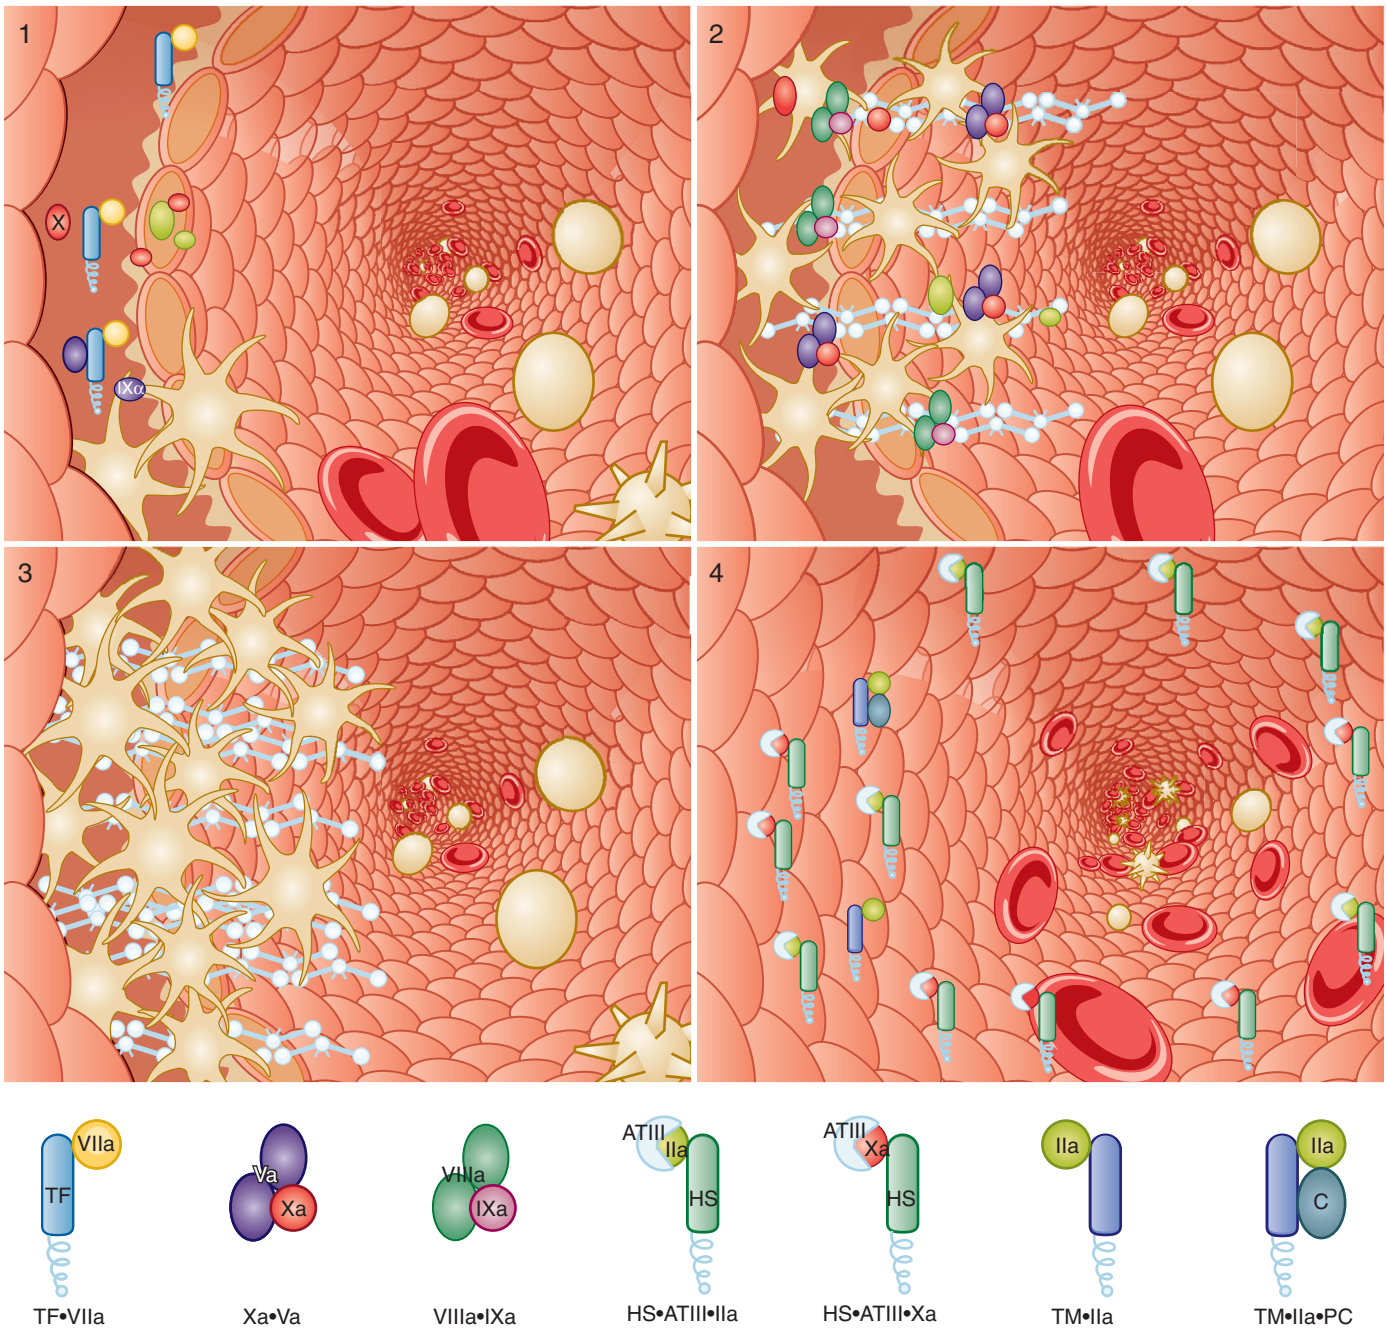

Figure 128-15 SCHEMATIC OF THE DYNAMIC EVENTS DURING TISSUE FACTOR–INITIATED BLOOD COAGULATION. A cross-section of a blood vessel showing the luminal space, endothelial cell layer, and extravascular region is presented at the site of a perforation. The blood coagulation process in response is depicted in four stages. *Extrinsic tenase* complex, TF (tissue factor) •VIIa; *prothrombinase* complex, Xa•Va; *intrinsic tenase*, VIIIa•IXa; AT (antithrombin)–endothelial cell heparan sulfate (HS) proteoglycan complex bound to thrombin or fXa, HS•AT•(IIa or Xa); protein C bound to thrombomodulin–thrombin, TM•IIa•PC.

Stage 1. Perforation results in delivery of blood, and with it circulating factor VIIa and platelets, to an extravascular space rich in membrane-bound TF. Platelets adhere to collagen and von Willebrand factor associated with the extravascular tissue, and TF binds factor VIIa, initiating the process of factor IX and factor X activation. Factor Xa activates small amounts of prothrombin to thrombin, which activates more platelets and converts factor V and factor VIII to factor Va and factor VIIIa.

Stage 2. The reaction is propagated by platelet-bound intrinsic tenase and *prothrombinase* with the former being the principal factor Xa generator. Initial clotting occurs and fibrin begins to fill in the void in cooperation with activated platelets.

Stage 3. A barrier composed of activated platelets ladened with procoagulant complexes and enmeshed in fibrin scaffolding is formed. The reaction in the now filled perforation is terminated by reagent consumption, attenuating further thrombin generation, but functional procoagulant enzyme complexes persist because they are protected from the dynamic inhibitory processes found on the intravascular face.

Stage 4. View downstream of the perforation. Enzymes escaping from the plugged perforation are captured by antithrombin–heparan complexes, and the protein C system is activated by residual thrombin binding to endothelial cell thrombomodulin, initiating the dynamic anticoagulant system. These intravascular processes work against occlusion of the vessel despite the continuous resupply of reactants across the intravascular face of the thrombus. *(From Orfeo T, Butenas S, Brummel-Ziedins KE, Mann KG: The tissue factor requirement in blood coagulation.* J Biol Chem *280(52):42887-42896, 2005, with permission.)*

Elimination and Fibrinolysis

The hemostatic or pathologic thrombus is structurally composed of aggregated platelets and crosslinked fibrin. The steps in thrombin generation of a crosslinked fibrin clot are shown diagrammatically in Fig. 128-11. Other plasma proteins and blood cells are also trapped within the clot. Clot formation is integrated with clot dissolution by plasmin to maintain hemostatic balance. The plasminogen system has two roles: t-PA generates plasmin at the fibrin surface and governs fibrin homeostasis, and u-PA binds to a cellular u-PA receptor (u-PAR) and generates pericellular plasmin, which plays an important role in tissue remodeling and cellular migration.[338,339] The latter function is, to a great extent, mediated by plasmin activation of matrix metalloproteinases (MMPs), which degrade ECM. t-PA and u-PA are secreted by vascular endothelial cells[340,341] and are regulated by cellular cytokines and components produced during the clotting cascade, including thrombin.

In the absence of fibrin, t-PA is a poor enzyme.[342-344] However, both t-PA and plasminogen bind to the fibrin surface with a resulting 100-fold enhancement in plasminogen activation. Thus, t-PA activation of fibrinolysis is primarily initiated by and localized to fibrin.[342,344] The digestion of fibrin by plasmin[345] is seen in Fig. 128-14 and further described under the section Fibrinolysis Proteins.[274,345-348]

Fibrinolysis is regulated primarily by PAI-1,[349,350] PAI-2,[351] α_2-antiplasmin, and TAFI.[352] The antagonism between PAI-1 and the plasminogen activators u-PA and t-PA provides a threshold response of the fibrinolytic process in much the same way as the procoagulant–anticoagulant balance provides an activation threshold for the clotting process.[353-356] α_2-Antiplasmin is the primary inhibitor of plasmin.[357-359] Plasmin, when bound through its lysine binding sites to fibrin, reacts more slowly with α_2-antiplasmin than when free in solution because α_2-antiplasmin interacts with plasma plasmin by binding to the lysine binding sites.[357-361] In contrast, α_2-antiplasmin, bound covalently by factor XIIIa to the Aα chain of fibrin, blocks plasmin binding and appears to decrease plasminogen activation.[362] TAFIa functions in vitro as an antifibrinolytic factor by suppressing the positive feedback pathway of fibrinolysis.[255,256,336]

The elimination phase begins the process of tissue repair by dissolving the fibrin–platelet clot generated in the earlier phases of hemostasis. The damaged vascular tissue not only requires plasmin to clear the fibrin clot but also to initiate removal of damaged tissue to allow for cell migration into the injured area.[363,364] Plasmin activates a variety of MMP that degrade subendothelial matrix components and extricate the damaged tissue.[364,365] These processes mark the beginnings of the final stages of the hemostatic response, repair, and regeneration.

The importance of the tight regulation of these processes is perhaps best illustrated by malfunctions of the hemostatic response. An inappropriate response can lead to one of two opposing but equally undesirable outcomes. Failure to form a sufficient hemostatic plug to arrest blood flow subsequent to vascular injury can result in pathologic hemorrhage. Excessive clot formation or failure to efficiently lyse a clot may result in thrombosis with consequent vascular obstruction. Under normal circumstances, the vascular endothelium together with the aforementioned positive and negative feedback loops within the procoagulant pathways prevent these negative outcomes by actively controlling the coagulation process until a triggering stimulus of sufficient magnitude threatens vascular integrity (Fig. 128-15). Initiation of the procoagulant response also initiates the fibrinolytic response simultaneously with repair and regeneration processes.

FUTURE DIRECTIONS

This chapter describes the process of blood coagulation (extrinsic and intrinsic pathway) by dividing it into sections based on procoagulant, anticoagulant and fibrinolytic enzymes, cofactors, and inhibitors in the overall process of fibrin formation and fibrin dissolution. When all of the players are present, the overall process of blood coagulation and fibrinolysis is best described as a dynamic threshold-limited, complex, intertwined process that together promotes hemostasis.

ACKNOWLEDGEMENTS

We the authors would like to thank Matthew Gissel, George Forguites, and Stacia Rymarchyk for their assistance in the preparation of this chapter. This work was funded by NIH 46703.

CHAPTER 129

REGULATORY MECHANISMS IN HEMOSTASIS

Charles T. Esmon and Naomi L. Esmon

Regulation of hemostasis can be divided into two areas: events that promote coagulation and events that inhibit this process.

KEY EVENTS IN THE PROMOTION OF COAGULATION

Key events that initiate and propagate coagulation are the redistribution of negatively charged phospholipids to the cell surface and the exposure of tissue factor to the blood. The appropriate negatively charged phospholipids, primarily phosphatidylserine, can arise as a result of either cellular activation with strong agonists like thrombin together with collagen in the case of platelets or tissue damage or death.[1,2] The negatively charged phospholipids promote the activation of factors X and IX by the tissue factor–factor VIIa pathway, the activation of prothrombin by factors Va and Xa, and the activation of factor X by factors VIIIa and IXa (see Chapter 128). In addition, it has been suggested that oxidation of a specific disulfide in tissue factor is important for expression of its procoagulant activity, a process that may be regulated by protein disulfide isomerase,[3,4] although this concept remains controversial.[5-8]

Normally tissue factor is not present on cells in contact with blood. Tissue factor is found on extravascular cells surrounding the blood vessel so that a potent procoagulant surface is exposed when the endothelium is breached. This helps to seal the breach.[9] Intravascularly, inflammatory stimuli can induce tissue factor synthesis and expression on leukocytes, particularly monocytes, providing a mechanism for the initiation of coagulation.[10] This response likely contributes to disseminated intravascular coagulation (DIC). Animal studies suggest that this coagulation response plays a role in innate immunity and prevents the dissemination of infectious agents.[11-14]

Other key events that can play a major role in the pathogenesis of thrombosis, at least in animal models, involve the release of intracellular components, including ribonucleic acid (RNA) and polyphosphates. These can trigger activation of factor XII, which initiates coagulation via the contact pathway. Although factor XII does not appear to contribute to hemostasis,[15] it drives several models of thrombosis, including pulmonary embolism[16] and myocardial infarction.[17]

Polyphosphates are stored in the dense granules of platelets and when released, contribute to the procoagulant potential of the platelet.[16] In regions of cellular death or severe inflammation, histones released from the tissue can bind to these polyphosphates, increasing the procoagulant activity more than 20-fold.[18] Heparin analogues can block polyphosphate stimulation of coagulation by histones.[18,19] In addition, neutrophils in hyperinflammatory environments can release their nuclear contents to form neutrophil extracellular traps (NETs). These NETs are effective in killing bacteria and other pathogens[20] and also provide a potent agonist for the activation of platelets and the development of thrombi.[19,21] Interestingly, heparin, an anticoagulant often used in the setting of inflammation, can disrupt the NETs and diminish the activation of platelets by histones and NETs.[19,21]

INHIBITION OF COAGULATION BY NATURAL ANTICOAGULANTS

There are three major natural anticoagulant mechanisms that serve to limit the coagulation process. These are tissue factor pathway inhibitor (TFPI), which blocks the initiation of coagulation by tissue factor-factor VIIa[22]; the antithrombin-heparin mechanism, which inhibits thrombin and factors VIIa, Xa, and IXa[23]; and the protein C pathway, which inactivates factors Va and VIIIa.[24]

Tissue Factor Pathway Inhibitor

TFPI is a complex molecule composed of three similar domains related to a protease inhibitor type known as a Kunitz inhibitor.[25,26] To inhibit the tissue factor–factor VIIa complex, the Kunitz-1 domain of TFPI binds factor VIIa, whereas the Kunitz-2 domain binds factor Xa, either because the factor X is activated on tissue factor[25,27] or (probably less effectively) by first reacting with factor Xa in solution and then inhibiting factor VIIa bound to tissue factor, thus blocking the initiation of coagulation (Fig. 129-1). The carboxy terminal portion of TFPI is very basic,[25] potentially facilitating interaction with the endothelium. Protein S, discussed in greater detail later, can augment the activity of TFPI[28] by increasing the rate of TFPI inactivation of factor Xa.[29]

TFPI exists in two forms, α and β, both found largely associated with the endothelium.[30] TFPIα is the intact form. In contrast, TFPIβ lacks the Kunitz-3 domain and the region that is C-terminal to this domain. TFPI in plasma is associated with lipoproteins and has considerably lower activity. Cellular TFPI is localized to intracellular granules and is found on the endothelial cell surface. Heparin can release TFPI from the endothelium.[31,32] It is unclear whether TFPI released from the endothelium contributes to the antithrombotic activity of heparin. Most likely, TFPIα is the most abundant form, but TFPIβ can bind to the endothelium via a glycosylphosphatidylinositol linkage, which appears to increase its inhibitory activity.[30] Incubation of endothelium with phospholipase D results in the release of both forms of TFPI, suggesting that either both forms are bound via the glycosylphosphatidylinositol linkage or, more likely, that a glycosylphosphatidylinositol–anchored TFPI binding partner is responsible for TFPI retention on the endothelium.[33]

The physiologic importance of TFPI is highlighted by the fact that gene deletion results in embryonic lethality apparently because of thrombosis and subsequent hemorrhage.[34]

Antithrombin

Antithrombin is the major inhibitor of the coagulation proteases thrombin, factor VIIa, factor Xa, and factor IXa. Antithrombin is a member of a large class of protease inhibitors referred to as serine

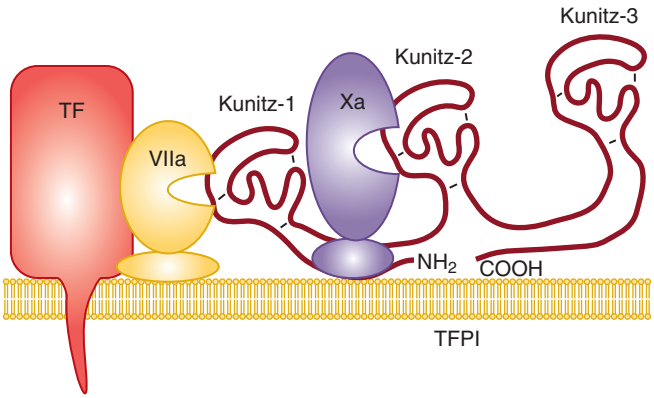

Figure 129-1 TISSUE FACTOR PATHWAY INHIBITOR (TFPI) FUNCTION. TFPI has three Kunitz domains, two of which function as protease inhibitors. The Kunitz-1 domain is responsible for inhibition of factor VIIa (VIIa) that is bound to tissue factor (TF). The Kunitz-2 domain inhibits factor Xa (Xa) either in solution or while the newly formed Xa is still associated with the activation complex. Inhibition of Xa concentrates TFPI in the vicinity of VIIa and facilitates VIIa inactivation. The complex dissociates when calcium ions are removed. *(From Esmon CT: Coagulation. In Fink MP, Abraham E, Vincent J-L, et al, editors:* Textbook of critical care, *ed 5, Philadelphia, 2005, Elsevier, p 165.)*

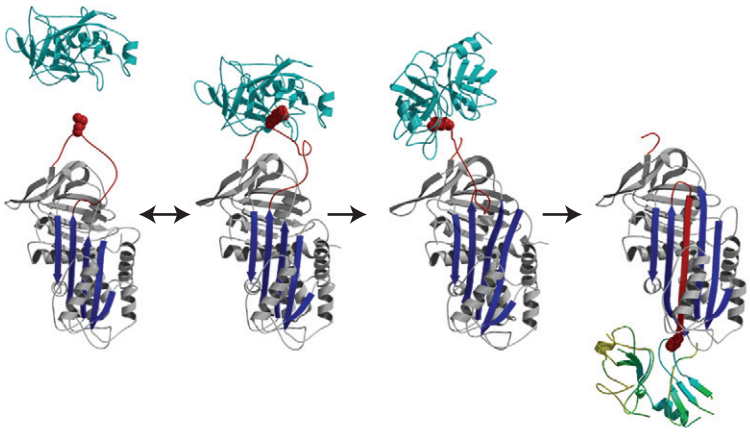

Figure 129-2 COMPLEX FORMATION BETWEEN A SERPIN AND AN ENZYME. Inactivation of trypsin by antitrypsin is shown. The mechanism of inhibition is the same for thrombin inhibition by antithrombin. To the left is the serpin with the major β-sheet A in blue and the reactive center loop with the scissile bond residue in red. The second section shows the formation of a Michaelis complex between the inhibitor and the enzyme, which results in the formation of a covalent inhibitor enzyme complex. The third section shows the complex with the cleaved reactive center loop. The final event is insertion of loop 4 (red) with linked enzyme into the β-sheet A with concomitant denaturation and inactivation of the enzyme (section 4). *(Modified from Huntington JA: Shape-shifting serpins—Advantages of a mobile mechanism.* Trends Biochem Sci *31:427, 2006.)*

protease inhibitors and abbreviated serpins.[35] Antithrombin forms a very tight complex with these proteases. This reaction is rather slow with a half-life in the order of 30 seconds in plasma. Heparin markedly accelerates the reaction, thus accounting for most of its anticoagulant activity. There is a "bait" region in antithrombin that is involved in its interaction with the proteases. In the absence of heparin, this bait region is only partially available to the protease, resulting in the slow inhibition. Heparin binding to antithrombin induces a conformational change in antithrombin that enhances protease access to the bait loop[36,37] (Fig. 129-2).

In addition to the conformational change in antithrombin, heparin has additional roles in the inhibition of coagulation proteases.

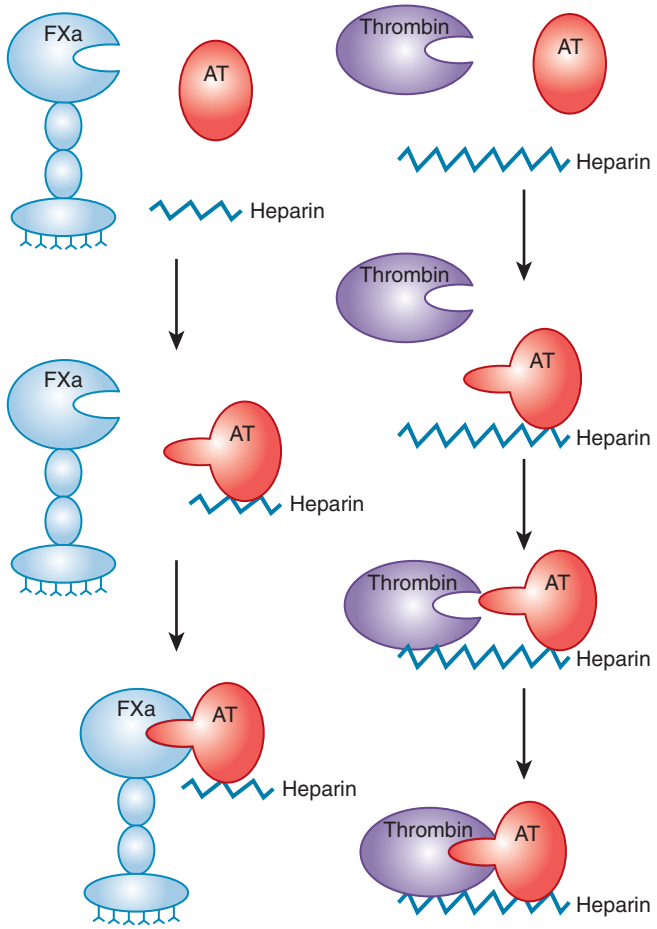

Figure 129-3 THE SIZE DEPENDENCE OF HEPARIN FUNCTION. Unfractionated heparin can simultaneously bind to both antithrombin (AT) and thrombin. This bridges the two together in what is commonly referred to as a template mechanism. This bridging is essential for rapid inactivation as is the binding to antithrombin, which induces a conformational change in antithrombin that is necessary but not sufficient for rapid thrombin inhibition. For factor Xa (FXa) inhibition, the conformational change in antithrombin is sufficient to induce rapid inactivation without an absolute need for bridging between the molecules. The only requirement for heparin here is that it contains the unique pentasaccharide sequence that mediates its binding to antithrombin, as is characterized by fondaparinux. Once the AT enzyme complex forms, heparin rapidly dissociates from the newly formed complex. *(Modified from Esmon CT: Coagulation. In Fink MP, Abraham E, Vincent J-L, et al, editors:* Textbook of critical care, *ed 5, Philadelphia, 2005, Elsevier, p 165.)*

High-molecular-weight (unfractionated) heparin can bind to both antithrombin and the protease, creating a situation where both reactants are brought into close proximity, thus increasing the reaction rate.[38] This function is of variable importance with different proteases of the cascade. It is essential for thrombin inhibition,[36,38] but plays a less important role in the inhibition of factor Xa[39] (Fig. 129-3). High-molecular-weight heparins accelerate factor Xa inhibition somewhat better than low-molecular-weight forms, but in contrast to most of the other heparin-mediated inhibitory functions, the additional acceleration gained by the high-molecular-weight forms is dependent on calcium ions.[39] It is of interest that as heparins become processed to generate lower-molecular-weight fractions, such as enoxaparin, the capacity to promote thrombin inhibition versus factor Xa inhibition decreases. With the smallest functional form of heparin, the synthetic pentasaccharide fondaparinux, the ability to augment thrombin inhibition is almost completely lost, while good inhibition of factor Xa is maintained.[40] Although heparin is a potent antithrombin-dependent anticoagulant, it is not effective against clot-bound thrombin[41] or the factor Va–factor Xa complex assembled on membrane surfaces.[42]

The importance of antithrombin is documented by the clinical observation that antithrombin deficiency, even to 50% of normal, is associated with significant thrombotic problems in humans[43] and mice.[44] Deletion of the gene in mice causes embryonic lethality, apparently in a mechanism that involves thrombosis followed by hemorrhage.[45] Although heparin-like proteoglycans have been proposed to be important in modulating antithrombin function, immunohistochemical analysis indicates that most of these are localized to the basolateral side of the endothelium.[46,47] No definitive deletion of heparin sulfate proteoglycans has been reported, possibly because there are alternative mechanisms for its biosynthesis.[48] However, deletion of ryudocan, another heparin-like proteoglycan, is associated with a thrombotic phenotype.[45]

The Protein C Anticoagulant Pathway

The protein C pathway serves many roles,[49,50] probably the primary role being to work to generate activated protein C (APC) that in turn inactivates factors Va and VIIIa to inhibit coagulation (Fig. 129-4). The importance of this anticoagulant activity is readily apparent because patients born without protein C die in infancy of massive thrombotic complication (purpura fulminans)[51,52] unless provided a protein C concentrate.[53,54]

The protein C anticoagulant pathway serves to alter the function of thrombin, converting it from a procoagulant enzyme into the initiator of an anticoagulant response.[49] This occurs when thrombin binds to thrombomodulin, a proteoglycan receptor primarily on the surface of the endothelium.[49] Thrombomodulin binds thrombin with high affinity (K_d approximately 1 to 10 nM), depending on the posttranslational modifications of thrombomodulin. Binding thrombin to thrombomodulin blocks most of thrombin's procoagulant activity such as the ability to clot fibrinogen,[55] activate platelets,[56] and activate factor V[55] but does not prevent thrombin inhibition by antithrombin.[57] The thrombin-thrombomodulin complex gains the ability to rapidly activate protein C. In the microcirculation, where there is a high ratio of endothelial surface to blood volume, it has been estimated that the thrombomodulin concentration is in the range of 100 to 500 nM.[49,58] Thus a single pass through the microcirculation effectively strips thrombin from the blood, initiates protein C activation, and holds a coagulantly inactive thrombin molecule in place for inhibition by antithrombin or protein C inhibitor.[59] Activation of protein C is augmented approximately 20-fold in vivo by the endothelial cell protein C receptor (EPCR).[60] EPCR binds both protein C and APC with similar affinity (K_d approximately 30 nM).[61] The EPCR-APC complex is capable of cytoprotective functions (see later), but at least with soluble EPCR, this complex is not an effective anticoagulant.[62] Instead, when APC dissociates from EPCR, it can interact with protein S to inactivate factors Va and VIIIa and thus inhibit coagulation[63] (see Fig. 129-4). Factor V increases the rate at which the APC–protein S complex inactivates factor VIIIa.[63]

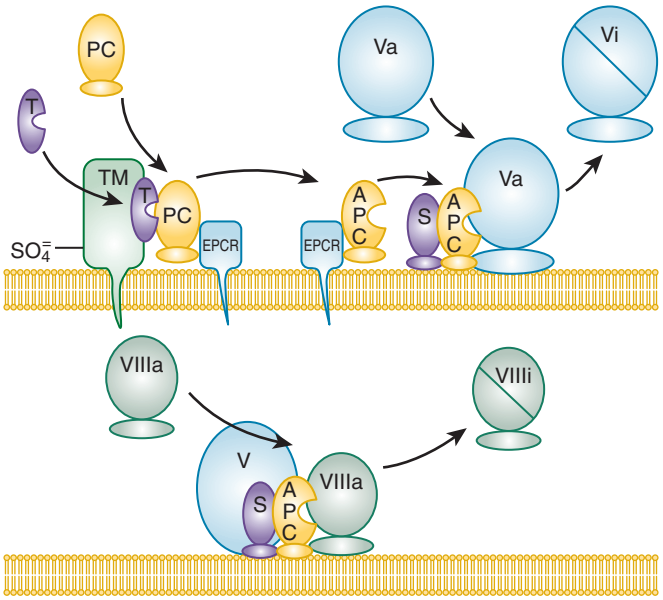

Figure 129-4 THE PROTEIN C ANTICOAGULANT PATHWAY. Thrombin (T) binds to thrombomodulin (TM) and activates protein C (PC). The activation is augmented by protein C binding to the endothelial cell protein C receptor (EPCR). Both protein C and activated protein C (APC) bind reversibly to EPCR. When APC dissociates from EPCR, it binds to protein S (S) and this complex inactivates factors Va (Va and Vi) and VIIIa (VIIIa and VIIIi). In the case of factor VIIIa, factor V (V) also increases the inactivation rate. *(From Esmon CT: Coagulation. In Fink MP, Abraham E, Vincent J-L, et al, editors:* Textbook of critical care, *ed 5, Philadelphia, 2005, Elsevier, p 165.)*

The ability of EPCR to bind both APC and protein C has interesting ramifications. By binding protein C, EPCR augments the conversion to APC and leaves the receptor "filled" with the active protease. APC bound to EPCR can cleave and activate protease activated receptor 1,[64] generating cytoprotective responses that are not only antiapopototic[50] and antiinflammatory[50] but also enhance endothelial cell barrier function.[65] Of interest, thrombin can cleave this same receptor, generating responses that are proinflammatory[66] and lead to loss of endothelial cell barrier function.[50] Although the responsible mechanisms are not yet fully elucidated, one mechanism appears to be that when APC binds to EPCR, it leads to cellular relocation out of the caveolae and then when the complex cleaves PAR1, the PAR1 becomes coupled to a different G (G1) protein that is responsible for the cytoprotective signaling.[67]

Thrombomodulin also inhibits complement activation and protects against complement-mediated organ damage.[68,69] It does so by facilitating the inactivation of complement C3b. Mutations in thrombomodulin that influence complement regulation, but not protein C activation, have been described and are associated with atypical hemolytic uremic syndrome.[69] Thrombomodulin also binds high mobility group box 1 protein, a proinflammatory molecule released from injured cells,[70] and directly neutralizes its inflammatory activity.[71]

In addition to regulating complement directly, thrombomodulin also increases the rate at which thrombin activates thrombin-activatable fibrinolysis inhibitor (TAFI) to a similar extent as it does protein C. TAFI is a procarboxypeptidase B–like enzyme that once activated, releases C-terminal lysine (Lys) and arginine (Arg) residues (with a kinetic preference for Arg).[72,74] C-terminal Lys residues on fibrin enhance fibrin degradation by serving as plasminogen– and tissue plasminogen activator–binding sites. Consequently, their removal by activated TAFI (TAFIa) attenuates clot lysis.[75]

Importantly, many vasoactive peptides, including complement anaphylatoxin C5a and bradykinin, have a C-terminal Arg residue that when removed results in the loss of biologic function.[72,76] Animal studies have suggested that TAFIa is a major mechanism by which these peptides are inactivated.[76]

Regulation of the Protein C Pathway

More than any other regulatory pathway except tissue factor, the protein C pathway is sensitive to regulation by inflammatory mediators (Fig. 129-5). Tumor necrosis factor-α and IL-1β downregulate thrombomodulin both in cell culture[49] and in at least some patients with sepsis.[77,78] Downregulation of thrombomodulin has been observed in animal models of diabetes,[79] inflammatory bowel disease,[80,81] reperfusion injury in the heart,[82] over human atheroma,[83] and in villitis,[84] in addition to sepsis.[77]

In patients with antiphospholipid syndrome, the protein C pathway can also be the target of autoantibodies that can inhibit pathway function and contribute to thrombosis.[85] Antibodies against

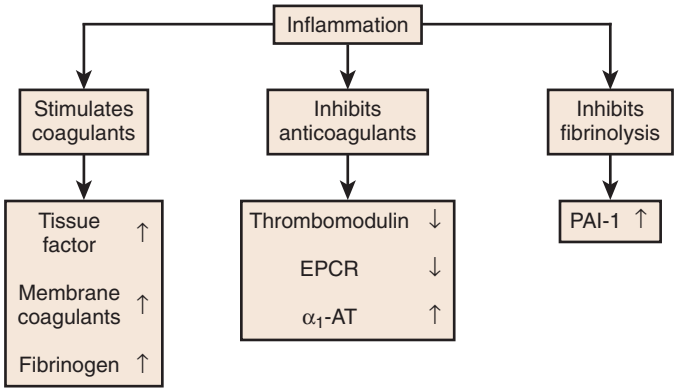

Figure 129-5 THE IMPACT OF INFLAMMATION ON THE REGULATION OF COAGULATION. Inflammatory mediators, such as TNF-α, downregulate thrombomodulin, the endothelial cell protein C receptor (EPCR), and vascular heparin-like molecules, resulting in a decrease in the natural anticoagulant pathways. *α_1-AT,* an inhibitor of APC, is upregulated. These same mediators upregulate tissue factor, triggering coagulation. Complement activation leads to the expression of procoagulantly active lipids on membrane surfaces, which facilitates the amplification of the response. Inflammation also leads to increased plasminogen activator inhibitor 1 (PAI-1) levels, resulting in downregulation of the fibrinolytic pathway. *α_1-AT,* α_1-Antitrypsin. *(Modified from Xu J, Lupu F, Esmon CT: Inflammation, innate immunity and blood coagulation.* Hamostaseologie *30:6, 2010.)*

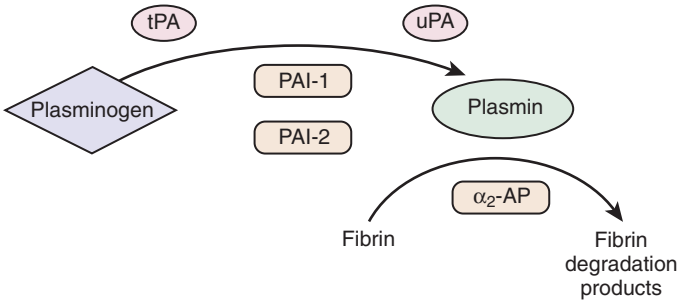

Figure 129-6 SCHEMATIC REPRESENTATION OF THE FIBRINOLYTIC SYSTEM. *α_2-AP,* α_2-Antiplasmin; *PAI,* plasminogen activator inhibitor; *tPA,* tissue plasminogen activator; *uPA,* urokinase plasminogen activator.

every protein involved in the pathway have been detected in selected patients. In addition, antibodies against β2-glycoprotein I, a hallmark of this syndrome, have been shown to inhibit the anticoagulant function of APC.[86] Those antibodies that activate endothelial or other cells and promote a prothrombotic state[87] or impair fibrinolysis[88] may also contribute to thrombosis.

Disease Modulation by Activated Protein C

APC can improve survival or organ function in animal models of inflammatory bowel disease,[79,89] diabetes,[79] myocardial reperfusion injury,[81] stroke,[90-92] and sepsis,[93] the latter being true for humans as well.[94] One of the complications of APC treatment in patients with sepsis is an increased risk for bleeding. In animal models of sepsis, mutant forms of APC that retain their cytoprotective activity, but have reduced anticoagulant activity, have been shown to reduce mortality.[95] These mutants have not been tested in humans.

Trauma results in massive injury, much of this to the microvasculature. To stem the thrombotic risk, protein C is activated. This occurs primarily in the microcirculation where, because of the vast surface to blood volume ratio,[49] the thrombomodulin concentration is extremely high.[49,96] Consequently, high levels of APC are generated in the microcirculation. This may contribute to the coagulopathy that is frequently observed in trauma patients.[97] Protein C levels decline, apparently because of the robust activation, and the APC is postulated to cause a systemic anticoagulant response, which exacerbates the coagulopathy.[97,98] In animal models of trauma, blocking protein C leads to organ dysfunction and death, whereas selectively blocking the anticoagulant activity of APC, but preserving cytoprotective activity, reduces the coagulopathy and improves survival.[99]

Protein S

Protein S circulates in two forms, free protein S and protein S that is tightly but reversibly bound to C4-binding protein, a regulatory protein of the complement system.[100-102] The APC cofactor function of protein S is blocked when it binds to C4-binding protein.[103] When protein S levels decrease in disease, the ratio of free and functional protein S relative to the inactive bound form decreases. Therefore, it is important to measure protein S activity as well as the antigen levels.[104]

Protein S accelerates factor Va inactivation. Importantly, it also alters the cleavage site preference on factor Va. Inactivation of factor Va requires cleavage of two bonds, one at 506 and the other at 306.[105] In a common dimorphism known as factor V Leiden, the cleavage site at 506 is mutated such that the Arg residue at 506 is replaced with a glutamine (Gln).[106] This mutation results in APC resistance and is associated with an increased risk for thrombosis.[24] Cleavage at 506 results in partial loss of factor Va activity, whereas cleavage at 306 results in complete loss of activity. Protein S accelerates the cleavage of the 306 bond, thereby reducing the impact of the factor V Leiden mutation.[107] In addition, factor V enhances APC-mediated inactivation of factor VIIIa,[63] whereas factor V Leiden lacks this ability.[108]

Protein Z and Protein Z–Dependent Protease Inhibitor

Protein Z is a vitamin K–dependent protein that works in concert with protein Z–dependent protease inhibitor and inhibits factor Xa, thereby attenuating coagulation.[109] Deletion of the protein Z gene in mice with factor V Leiden leads to a prothrombotic phenotype.[110] A possible association between genetic defects in protein Z–dependent protease inhibitor and thrombosis has been reported.[111]

REGULATION OF FIBRINOLYSIS

Fibrinolysis is the process by which fibrin clots are dissolved, either through natural mechanisms or with the aid of pharmaceutical interventions. Plasmin is the serine protease that solubilizes fibrin. Plasmin is generated by the activation of its precursor plasminogen either by natural activators, tissue plasminogen activator (tPA),[112] the major activator in the circulation, or urokinase plasminogen activator (uPA)[113] (Fig. 129-6), or by administration of recombinant tPA or streptokinase, a bacterial protein that promotes plasmin generation and aids in dissemination of the bacteria.[13] Staphylokinase, a protein from *Staphylococcus aureus,* is similar to streptokinase and also has been examined as a potential therapeutic.[114]

Fibrin plays an active role in its own degradation because it binds plasminogen and tPA, thereby concentrating them on the fibrin surface and promoting their interaction. The resultant plasmin cleaves fibrin and exposes C-terminal Lys residues that serve as additional plasminogen and tPA binding sites. TAFIa attenuates fibrinolysis by releasing these C-terminal Lys residues.[74] Furthermore, Lys analogues, such as ε-aminocaproic acid or tranexamic acid, bind to tPA and plasminogen. Consequently, these Lys analogues can be used to treat patients with hyperfibrinolysis and can reduce bleeding complications.[115]

Plasmin is not specific for fibrin and degrades a variety of other proteins. Consequently, plasmin is tightly controlled. There are two major inhibitors of fibrinolysis: α_2-antiplasmin,[116] a serpin that inactivates plasmin, and plasminogen activator inhibitor 1 (PAI-1), which inhibits tPA and uPA.[117] α_2-Antiplasmin is cross-linked to fibrin by activated factor XIII.[116] PAI-1 is an intrinsically unstable serpin that can be stabilized by interaction with vitronectin.[118,119] Because of its instability, the antigen and functional levels of PAI-1 are often quite different and can vary among individuals. PAI-1 is upregulated by lipopolysaccharide, tumor necrosis factor, and other inflammatory cytokines. PAI-1 levels are increased in vascular diseases such as atherosclerosis and in metabolic syndrome, sepsis, and obesity.[117] Increased levels of PAI-1 result in decreased fibrinolytic activity, which increases the risk for thrombosis. PAI-1 is also stored in platelets and is released with platelet activation.[117] Platelet-derived PAI-1 may limit the degradation of platelet-rich thrombi, such as those that trigger acute coronary syndromes.

Overall the fibrinolytic system is dynamic and responsive to local phenomena, such as platelet-derived PAI-1, as well as to systemic alterations like obesity and inflammation.[117] In this sense, the fibrinolytic control mechanisms share many similarities with the control of coagulation, in which similar considerations affect their function.

CHAPTER 130

CLINICAL APPROACH TO THE PATIENT WITH BLEEDING OR BRUISING

Catherine P.M. Hayward

Bruising and bleeding problems are common reasons for a hematology referral.[1] The management of an acute bleed (e.g., life-threatening hemorrhage from an acquired factor VIII inhibitor, an anticoagulant drug, or a postpartum hemorrhage) should be the first priority because diagnostic test results are often not immediately available. Most assessments of bruising and bleeding symptoms are not urgent, but they can be challenging because individuals without bleeding problems often experience bleeding symptoms (e.g., bruising with trauma, nosebleeds).[1-3] Furthermore, most individuals referred for assessment of bleeding problems have experienced some bleeding symptoms.[3] In addition, many individuals referred for bleeding symptoms have bleeding disorders; consequently, there is a high pretest probability for a bleeding disorder among such patients.[3]

Some referrals for bleeding disorder assessments are for asymptomatic problems (e.g., abnormal coagulation tests due to vitamin K deficiency, evaluation of a familial bleeding problem after diagnosis of other relatives). Mild bleeding symptoms (e.g., bruising, nosebleeds, possible abnormal bleeding with prior surgery) are more common than severe symptoms (e.g., severe bleed from anticoagulant therapy, life-threatening postpartum hemorrhage) among referred individuals. Sometimes the bleeding symptoms reflect an underlying bone marrow disorder (e.g., bleeding and thrombocytopenia due to leukemia or a platelet function defect induced by a myelodysplastic or myeloproliferative syndrome). Some causes of bleeding, such as vitamin C deficiency (scurvy), are rare in developed countries. For all assessments for bleeding or bruising, it is important to assess symptoms that are concerning to the patient and/or physician and the range of bleeding symptoms/problems that the person has or has not experienced when considering possible causes.[1,3] The next step is to formulate a differential diagnosis and plans for bleeding symptom management (e.g., control of menorrhagia), including strategies to minimize future bleeding risks.[3]

Fig. 130-1 provides a general guide to the steps in a clinical assessment. Bleeding-history assessment tools provide a detailed framework to evaluate the medical history and to determine which symptoms should be considered more suspicious of an underlying bleeding problem.[4-8] Unfortunately, none of the published bleeding-history assessment tools has been prospectively validated for ruling in, or ruling out, a bleeding disorder at the time of an initial assessment for bleeding problems[4] (see box on Influences on Presenting Problems). A very high bleeding score is consistent with a bleeding problem.[4-7,9] However, there is overlap of scores for individuals with and without bleeding problems.[4,5] These tools provide evidence that some bleeding symptoms are uncommon unless there is a bleeding disorder (e.g., joint bleeds, bruises that are as large or larger than an orange or that track downward).[2,4,7,8] Nonetheless, further research is needed to develop tools with acceptable utility for ruling in or ruling out bleeding disorders at the time of an initial assessment (see box on Case 1: Illustration of a Mild, Inherited Bleeding Problem).

Some bleeding symptoms, such as menorrhagia or nosebleeds, are not specific to any particular type of bleeding problem.[1,3,7] Bleeding can be triggered or exacerbated by therapies for atherosclerotic disease (aspirin and/or $P2Y_{12}$ inhibitors, inhibitors of $\alpha_{IIb}\beta_3$), venous thrombotic disease (prophylaxis or treatment with anticoagulants), inflammatory states (e.g., treatment with prednisone or other glucocorticoids) and pain (prescription or nonprescription use of nonsteroidal antiinflammatory drugs [NSAIDs]).[1,3] Bruising can also reflect topical corticosteroid use and/or age-related changes in the skin (i.e., senile purpura).[1,3]

Without treatment, severe bleeding disorders typically cause abnormal bleeding with all major hemostatic challenges. On the other hand, bleeding may not occur with every challenge in persons with mild defects and lower bleeding risks (e.g., those with a 5- to 10-fold increased risk for bleeding). Age influences the bleeding history by increasing the likelihood of exposures to hemostatic challenges and the development of sequelae such as arthropathy in patients with severe hemophilia.[6,7] A severe bleed with surgery that is unexplained may be considered suspicious of a bleeding problem. However, if the person reports that prior challenges did not result in bleeding, this narrows down the possibilities to a mild inherited bleeding disorder, an acquired bleeding disorder, or an iatrogenic condition (e.g., bleeding while on anticoagulant therapy or a technical problem during surgery that caused bleeding). A bleeding-disorder assessment needs to consider both familial and personal bleeding symptoms (see box on Case 2: Illustration of the Importance of Assessing Both Personal and Familial Bleeding Problems).

The timing of bleeding with challenges is evaluated to assess whether the bleeding problem reflects a common bleeding disorder, such as von Willebrand disease, a platelet function disorder, an undefined mucocutaneous bleeding problem, or a rarer cause, such as a defect or deficiency in a coagulation factor or fibrinolytic protein[1,3] (see box on Case 3: Illustration of the Importance of Assessing Bleeding Problems Over Time; see also boxes on Cases 1 and 2). Although patients will often know whether bleeding began on the day of a challenge, their recall of timing details is often better when procedures were done without general anaesthesia (e.g., dental extractions, biopsies).[1,3,7] Bleeding within a few hours or on the same day of a challenge (e.g., surgery or dental extraction) is most suggestive of a defect involving von Willebrand factor or platelets.[1,3,7] Delayed bleeding (beginning 1 or more days after a challenge) is most suggestive of a coagulation or fibrinolytic defect (see boxes on Cases 1 and 2).[1,3,7] However, the onset of some bleeding, such as postpartum hemorrhage, can be delayed in persons with von Willebrand disease or platelet function disorders.[1,3,10-14] Postpartum bleeding may be absent in mild bleeding disorders because pregnancy increases the levels of some hemostatic proteins, including fibrinogen and von Willebrand factor. Bleeding during pregnancy, after implantation, is uncommon with most bleeding disorders, although it can be severe in individuals with bleeding disorders who develop placental abruption (e.g., from an untreated fibrinogen disorder or factor XIII deficiency). Intracranial bleeding in a child may suggest a severe defect or deficiency of factor XIII, a coagulation factor deficiency, or a fibrinolytic inhibitor, but other conditions should be considered if the diagnostic tests for these conditions are negative.

EPIDEMIOLOGY

An understanding of the epidemiology of bleeding problems requires distinction between symptoms that rarely represent a pathologic condition and do not require investigation or therapy (e.g., isolated "easy bruising") and those that are more suspicious, require treatment, and/

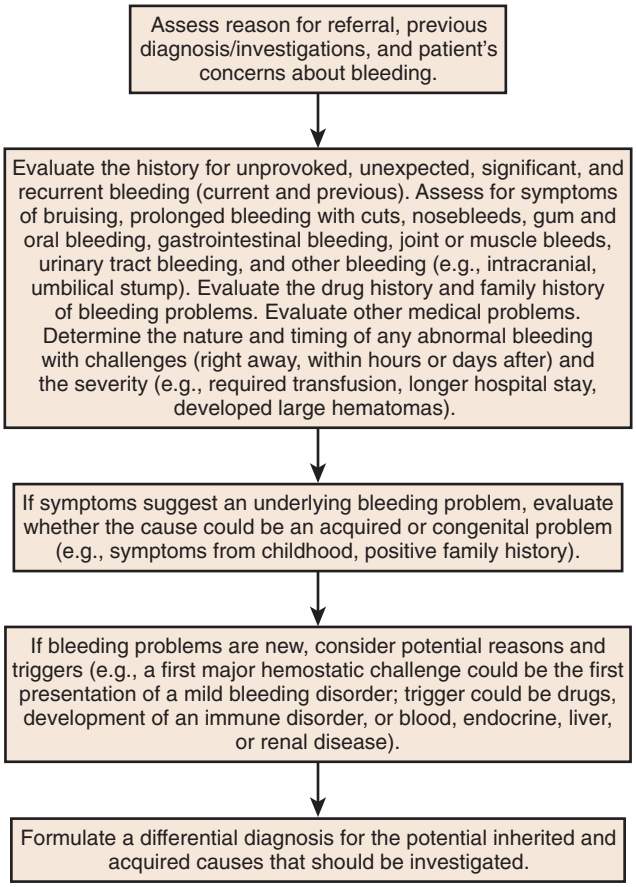

Figure 130-1 STEPS TO EVALUATE BLEEDING AND BRUISING PROBLEMS.

Influences on Presenting Problems

When evaluating a bleeding history, it is important to recognize that the presenting problems are influenced by the following:

1. The nature and severity of the defect, the presence of a single or multiple risk factors for bleeding
2. Whether the bleeding problem is congenital or acquired
3. Antecedent exposures to hemostatic challenges (such as surgery, dental extraction, menses, and childbirth) and the risk for bleeding with each of these challenges
4. The presence of other medical problems (e.g., renal, liver, or thyroid disease), including anemia
5. Variability in the bleeding symptoms experienced by individuals without bleeding problems (e.g., nosebleeds, bruising) and by individuals with known bleeding disorders, even within families with the same defect
6. Local factors (e.g., vascular lesions, diverticular disease, or cancerous lesions in the gastrointestinal tract)
7. Treatments that increase the risk for bleeding (e.g., nonsteroidal antiinflammatory drug [NSAID] use for pain control, anticoagulant therapy, etc.)
8. Whether treatments were used to prevent or control bleeding, or if they reduced bleeding when prescribed for other reasons (e.g., reduced menstrual bleeding while on oral contraceptives to prevent pregnancy)

Case 1: Illustration of a Mild, Inherited Bleeding Problem

A 77-year-old man who is starting treatment for multiple myeloma was discovered to have a prolonged activated partial thromboplastin time (aPTT). Review of his records indicated that the abnormality was present on a previous admission for spinal cord compression, which was treated with surgery. He required 4 units of packed red blood cells several days after this surgery because of delayed postoperative bleeding. There was no other bleeding history. He was found to have mild factor IX deficiency, unrelated to the myeloma, and his daughter proved to be a carrier of this defect.

Case 2: Illustration of the Importance of Assessing Both Personal and Familial Bleeding Problems

A 22-year-old woman was referred for evaluation of a possible platelet disorder. She had a history of menorrhagia (3 to 4 days out of 7 days of flow were heavy when not on treatment), prolonged nosebleeds in childhood, and hematuria only with urinary tract infections. She did not have thrombocytopenia, and she had no exposure to major hemostatic challenges. Her father, uncle, and grandfather had a striking bleeding history, and two of them had thrombocytopenia. The bleeding in her relatives included joint bleeds with trauma and severe, delayed-onset bleeding after trauma and surgery (usually more than a day later), which continued for weeks despite platelet transfusions. One of these relatives reported no bleeding when he had a tooth extracted while receiving fibrinolytic inhibitor therapy. Although menorrhagia is not specific to any one type of bleeding disorder, the delayed bleeding in affected relatives suggests a possible autosomal dominant disorder and either a fibrinolytic defect or a factor deficiency (the latter had been excluded in previous tests of the affected relatives). Because of the history of thrombocytopenia, joint bleeds, and delayed bleeding, which did not respond well to platelet transfusions, testing was done for the Quebec platelet disorder. The referred patient and her relatives were confirmed to have this disorder by genetic testing for duplication mutation of the urokinase plasminogen activator gene. This case illustrates the importance of evaluating both the personal and family bleeding history and highlights the fact that bleeding-symptom severity can vary among affected family members, in part because of their different exposures to challenges and treatments.

Case 3: Illustration of the Importance of Assessing Bleeding Problems Over Time

A 72-year-old man was referred for evaluation of a severe bleed after receiving a single dose of low-molecular-weight heparin for unconfirmed deep vein thrombosis. He had a history of a similar bleeding episode several years previously while on warfarin treatment for atrial fibrillation. There was no other bleeding history, and the patient subsequently developed a spontaneous iliopsoas bleed. He had undergone numerous surgeries earlier in life without any bleeding problems, and there was no family history of bleeding. The bleeding history suggested the possibility of an acquired bleeding problem, possibly acquired von Willebrand disease or an acquired factor deficiency. Diagnostic testing indicated that he had acquired factor XIII deficiency. This case illustrates the fact that more than one risk factor for bleeding can coexist: in this case, several exposures to anticoagulants triggered bleeding in a patient with an acquired factor deficiency. On initial treatment of his iliopsoas bleed with factor XIII concentrates there was partial neutralization of the infused factor followed by accelerated clearance, consistent with acquired factor XIII deficiency secondary to an autoantibody.

or are highly predictive of a bleeding problem.[1,3] Some individuals have multiple risk factors for bleeding (e.g., low von Willebrand factor levels, exposure to drugs that inhibit platelet function after a surgical procedure associated with a high risk for bleeding).[3] Although some symptoms, such as nosebleeds, easy bruising, and menorrhagia, are quite prevalent in the general population (10% or more report these symptoms), these problems are more frequent and more severe in individuals with bleeding disorders.[1-4,7,10,15,16] Menorrhagia requiring treatment is common among women, and it can be life-threatening in severe bleeding disorders.[11,15,17,18] With moderate or severe disorders, there is less debate about the disease prevalence than there is for milder disorders (e.g., type 1 von Willebrand disease) where there is ongoing debate about the diagnostic criteria that define a pathologic abnormality.[10] There is less information on the prevalence of disorders that require complex tests for diagnosis and have many potential causes (e.g., platelet function disorders). Undefined disorders (definite bleeding problems despite normal or nondiagnostic test findings) have emerged to be a common cause of mucocutaneous bleeding.[19,20]

The process of a referral for bleeding makes it quite likely that the person has had some bleeding symptoms that may or may not reflect an underlying congenital or acquired bleeding problem.[1,3] Because of this referral bias, the prevalence of bleeding disorders in tertiary referral clinics is much higher than in the general population. The prevalence of inherited bleeding disorders in the general population is quite low (from 0.00023% to over 1% for von Willebrand disease, with much lower estimates based on studies of bleeding disorder–clinic cases compared with those derived from population screening using higher cutoffs to define quantitative deficiencies; 0.005% to 0.01% for hemophilia; and much lower for other coagulation factor deficiencies). Consequently, unselected screening is not recommended.[1,3,10,21] Founder effects in populations can alter the prevalence of both common and rare inherited bleeding disorders.

A person with a first-degree relative with an autosomal dominant bleeding problem, or a sibling with a recessively inherited disorder, has a higher pretest probability for an inherited bleeding disorder.[7,10] When assessing the relative of someone with a positive family history of a bleeding problem, it is important to realize that the person may have the same condition or a different bleeding problem.[7] Furthermore, it is common for affected family members to show some variability in the severity of their bleeding symptoms.[7,10] Index cases typically have more bleeding symptoms.[1,4] Accordingly, laboratory investigations are often used to assess family members at high risk, even in the absence of a remarkable personal bleeding history.

Common bleeding disorders that are inherited as autosomal dominant traits include von Willebrand disease, many common platelet function disorders (including secretion defects, MYH9-related disorders, gain-of-function disorders such as platelet-type von Willebrand disease and Quebec platelet disorder), and dysfibrinogenemia.[1,3,10,16] Because the diagnostic criteria for mild von Willebrand disease have changed,[10] a positive family history often requires reevaluation.

X-linked bleeding disorders include hemophilia A, hemophilia B, and X-linked congenital platelet disorders (e.g., Wiskott-Aldrich syndrome or thrombocytopenia due to GATA1 mutations).[1,3,16] X-linked disorders typically affect males but can affect women with skewed X-chromosome inactivation or Turner syndrome. Recessively inherited bleeding disorders are the most rare, and their prevalence is highest in populations in which consanguinity is culturally accepted.[22]

Acquired bleeding problems are common, and the most frequent cause is a drug-induced defect.[1,3] Drugs that alter hemostasis may cause bleeding on their own or unmask symptoms from a mild or moderate underlying bleeding disorder.[1,3,23] Drug-induced problems to consider include the following: (1) use of prescription or nonprescription NSAIDs that transiently inhibit platelet cyclooxygenase-1 (COX-1) (patients may not recall taking these drugs if they received them after a surgical procedure[3,23]); (2) aspirin or $P2Y_{12}$ or $\alpha_{IIb}\beta_3$ inhibitors used for acute or chronic prevention or treatment of cardiovascular disorders; (3) anticoagulants prescribed for the prevention or treatment of venous thromboembolic disease, atrial fibrillation, or acute management of atherosclerotic disease; (4) antidepressant medications (e.g., serotonin reuptake inhibitors), which may cause bruising symptoms; and (5) glucocorticoid therapy.[1,20,24,25] Some dietary practices affect platelet function (e.g., use of fish oil supplements, ingestion of herbal supplements with aspirin-like properties), as can acute alcohol intoxication.[3,16]

Among adults with von Willebrand disease, factor VIII deficiency, and factor XIII deficiency, about 10% of the cases are due to an acquired, autoantibody-induced deficiency state. Autoimmune causes of other bleeding disorders include immune thrombocytopenia, immune-mediated platelet dysfunction (more commonly due to antibodies against glycoprotein IbIXV or $\alpha_{IIb}\alpha_3$), and acquired factor V deficiency.[1,3] Bone marrow disorders are associated with an increased risk for autoimmune or nonimmune bleeding problems, including thrombocytopenia, secondary platelet function defects of diverse etiology (e.g., acquired forms of dense granule deficiency, Glanzmann thrombasthenia, or Bernard-Soulier syndrome), or acquired von Willebrand disease.[16] Acquired bleeding problems can also accompany the development of renal disease, liver disease, hypothyroidism, or Cushing syndrome.[1,3]

PATHOBIOLOGY

There are many different components of the hemostatic, fibrinolytic and vascular response to injury that are important for prevention and control of bleeding (see Chapters 123, 124, 125, 127, and 128). Normal hemostasis requires platelet adhesion to collagen and aggregate formation at sites of tissue injury, which requires von Willebrand factor and other adhesive proteins; the initiation of coagulation by tissue factor; followed by amplification and propagation of coagulation to generate thrombin and convert fibrinogen to fibrin. It also requires stabilization of fibrin through the cross-linking actions of activated factor XIII. The activation of fibrinolysis (which is important for wound healing) is part of the normal response to tissue injury and repair. Fibrinolysis is retarded by platelets (which release large quantities of stored plasminogen activator inhibitor 1 [PAI-1]) and accelerated by deficiencies or defects in PAI-1 or α_2-antiplasmin, gain-of-function defects in plasminogen activators, and pathologic states that increase fibrinolysis. The interdependence of hemostatic mechanisms explains why a failure of platelet adhesive mechanisms (e.g., from defects in platelet number or function or von Willebrand disease) may cause persistent, delayed, and/or recurrent bleeding from a wound site, particularly if initial hemostasis was inadequately managed. That activation of fibrinolysis occurs during hemostasis explains why fibrinolytic inhibitors are often effective for treating diverse bleeding problems (e.g., menorrhagia and bleeding from oral/nasal surgical or dental procedures) in patients with conditions from von Willebrand disease and platelet disorders to factor deficiencies and fibrinolytic defects. Some individuals with severe nosebleeds or gastrointestinal bleeds from platelet function disorders (e.g., Glanzmann thrombasthenia) that are refractory to platelet transfusions (because of development of antibodies) may respond to treatment with recombinant factor VIIa.

Hemostasis is also influenced by other factors, such as anemia. The red cell concentration in blood influences platelet margination, which allows platelets to adhere to the injured vessel wall. Accordingly, anemia can worsen bleeding. Some disorders of hemostasis reflect defects in the vessel wall. For example, hereditary hemorrhagic telangiectasia (which does not always present with obvious skin or oral vascular lesions)[26] can cause troublesome bleeding from sites where the vascular malformations are located. These lesions can cause recurrent epistaxis, gastrointestinal bleeding, and less commonly, intracranial or pulmonary hemorrhage typically without causing bleeding with surgical procedures or menorrhagia.[1,3]

CLINICAL MANIFESTATIONS

Age of Presentation and Extent of Symptoms

Inherited bleeding disorders can present at any age, but if severe, a bleeding disorder typically presents at a younger age.[1,3,6,7,27] Milder

disorders can present at any age and may require a significant hemostatic challenge to come to medical attention, often a major surgical procedure or a dental extraction.[1,3,6,7,27] Women with mild, moderate, or severe inherited bleeding disorders may present with troublesome bleeding at the onset of menses or with childbirth-related bleeding.[1,3,7,27] When the bleeding risks are only mildly increased (e.g., low von Willebrand factor levels without other defects, a mild inherited platelet secretion defect), there may be a history of bleeding with some, but not all, hemostatic challenges.[1,3,10]

The severity of a bleeding disorder affects the number, severity, and type of manifestations. Numerical scores, derived from standardized bleeding-history assessment tools, show considerable overlap among subjects with different disease severities.[4] Although use of a standardized tool has been recommended by the International Society on Thrombosis and Haemostasis,[5] the tool has yet to be prospectively validated for use in clinical practice.

Family History and Syndromic Disorders

It is important to consider that the family history for an inherited bleeding disorder is influenced by the disorder severity and the mode of inheritance and whether there is a single or multiple bleeding disorders in the family. The family history is often negative if the cause is an acquired problem, such as iatrogenic bleeding from anticoagulant therapy or a technical problem complicating a surgical or dental procedure.[1] The family history is typically positive when the disorder is autosomal dominant and has high penetrance.[3,7,10] The family history is negative in individuals with novel mutations and in those with recessive disorders unless there are affected siblings or many affected relatives from consanguinity or founder effects. Individuals with mild disorders who have never had a hemostatic challenge may be referred after another family member is identified to have a bleeding problem or if the person has bleeding after a significant hemostatic challenge.[1,3] Early identification of a disorder may alter the natural history, particularly if treatment is given before hemostatic challenges.[7]

Some patients have other clinical problems that suggest the possibility of a syndromic disorder (e.g., albinism or a history of delayed pigmentation, hearing loss, nephritis, absent radii) or an alternative diagnosis (e.g., hyperextensibility due to Ehlers-Danlos syndrome).

Bruising, Petechiae, and Other Skin Changes

Bruising (which reflects bleeding into the skin) is a very commonly reported bleeding symptom.[3,4,7,10,16] Bruising is reported more frequently by women than men.[2]

Some bruising symptoms are more suggestive of a bleeding problem than others. For example, bruises from bleeding disorders often occur after minimal or no recalled trauma.[3,4,7,10,16] Bruises that are unusually large (e.g., as big or bigger than an orange) or lumpy or that migrate (i.e., track downward to the feet over time) are consistent with more extensive bleeding into cutaneous or subcutaneous tissues and are more specific, but not highly sensitive, for bleeding disorders.[4,7,10] When bruises are large or multiple, patients may hide them (by wearing pants and long-sleeve shirts) to avoid being questioned. Severe bruising symptoms may lead to lifestyle changes (e.g., avoidance of sports or other activities that increase the risk for bruising).[7] When there is significant swelling with a bruise, imaging (e.g., by ultrasound) may be necessary to exclude bleeding into deeper tissues.

Bruising symptoms (that are normal or abnormal) can fluctuate, depending on activity levels and exposure to drugs or trauma that increase bruising risks (e.g., increased bruising when moving house, traveling, or engaging in physical sports; bruising in a toddler who just started walking; worsened bruising after initiating antidepressant therapy). Like normal bruising, bruising from bleeding disorders usually occurs at sites that are commonly exposed to trauma (e.g., lower limbs, outer hips, arms). However, bruising with acquired hemophilia A may be extensive and involve other regions (e.g., the trunk). This type of bruising is probably autoantibody related because it does not occur in congenital hemophilia, even if there is an inhibitor.

An examination of the skin sometimes reveals bruising associated with skin pigmentation changes from iron deposition. This is typical of repeated bleeds in persons with severe platelet function disorders or moderate to severe forms of von Willebrand disease. These pigment changes are typically localized to sites of recurrent trauma (e.g., anterior shins), and the distribution (which can be spotty) helps to distinguish the finding from the pigmentation associated with venous stasis.

Petechiae and/or oral blood blisters are typical of severe thrombocytopenia and are less commonly seen in other conditions, including severe platelet function disorders. Scurvy can cause perifollicular hemorrhages (often on the shins), bruising, and gum bleeding, typically with associated swelling and redness. Schamberg disease is a pigmented purpuric dermatitis that does not represent a bleeding problem and can be mistaken for petechiae. Early lesions of purpura fulminans, from congenital deficiency of protein C or protein S, may be mistaken for bruises, but the age of the patient and the distribution of the lesions help to establish the diagnosis. Skin bleeding from minor lesions (e.g., skin cancers) can be unusually troublesome for patients with a severe bleeding disorder.

Epistaxis

Epistaxis is a commonly reported bleeding symptom that does not always reflect a bleeding disorder, even when the bleeding is frequent and/or requires medical interventions.[2-5,7] Although nosebleeds can be due to mucocutaneous bleeding disorders (e.g., platelet or von Willebrand factor problems), they can also be due to severe deficiencies of common pathway coagulation factors (e.g., congenital deficiency of factor V, factor X, or prothrombin), fibrinolytic defects (PAI-1 or α_2-antiplasmin deficiency, increased platelet urokinase plasminogen activator [uPA] from Quebec platelet disorder) or hereditary hemorrhagic telangiectasia.* Nosebleeds, from bleeding disorders or other causes, are often worse in childhood.

When the volume of bleeding from the nose is large, the patient may experience passage of clots, anteriorly and posteriorly, sometimes with melena. Although nosebleeds are not specific to bleeding disorders, it is important to ask about them because severe nosebleeds can be disabling for some individuals with bleeding disorders, such as von Willebrand disease.[3,10]

Gum Bleeding and Bleeding With Loss of Primary Teeth

Gum bleeding can be problematic with inherited or acquired bleeding disorders that affect platelets or von Willebrand factor, although it more frequently reflects gum disease.[1,3,10,22] Severe bleeding with the loss of primary teeth is also suspicious of an underlying bleeding disorder.*

Gastrointestinal Bleeding

Gastrointestinal bleeding can complicate a bleeding disorder, but it is rarely the presenting problem, and it requires investigation to determine the source of the bleeding.[1,3,4,10] Gastrointestinal bleeding can be severe with hereditary hemorrhagic telangiectasia.[26]

Challenge-Related Bleeding

The assessment of challenge-related bleeding is an important part of taking a bleeding history. Bleeding related to accidental trauma may

*References 1, 3, 7, 10, 16, 22.

be more difficult to evaluate than bleeding associated with surgery or dental procedures because accidental trauma often causes bleeding, and it is difficult to determine whether the extent of bleeding was excessive.[7] In addition, large wounds may continue to bleed until sutured.

A history of bleeding with surgical or dental procedures can include being told that there was excessive bleeding by a dentist, physician, or other health care worker and/or experiencing: excessive oozing or drainage from incision or extraction sites; wound hematomas; delayed wound healing; bleeding requiring repeated surgery, suturing of an extraction site, an admission to hospital, a longer hospital stay, and/or transfer to the intensive care unit; and receiving blood transfusions, drugs, and/or factor replacement for hemorrhage control.[1,3,7] Patients may not spontaneously report some symptoms, such as extensive bruising around surgical incisions. Occasionally an operative report or other medical document provides important confirmation that there was abnormal bleeding with surgery (e.g., an operative note that documents generalized oozing during a procedure and greater-than-expected total blood loss).[1,3] Iatrogenic reasons (e.g., oozing vessels that were not cauterized or ligated) should be considered when there is a history of an isolated bleeding episode.

Many individuals undergo dental extractions at some point in their life. Bleeding that persists beyond the first day, or that becomes problematic one or more days after a dental extraction, should be considered suggestive of a bleeding disorder.[1,3] Severe bleeding with dental cleaning should be considered suggestive of a congenital or an acquired bleeding disorder (e.g., von Willebrand disease or a platelet function disorder).

In individuals with a moderate-to-severe bleeding problem, bleeding after surgery, dental procedures, or a severe throat infection can lead to airway compromise, whereas bleeding from a surgical or traumatic limb injury can lead to compartment syndrome.[1,3,28]

Bleeding Symptoms Restricted to Women

Women with bleeding disorders experience more bleeding than men because of the hemostatic challenges associated with menses and childbirth.[17,29] Such women are also at increased risk for developing endometriosis and hemorrhage from ovarian cysts.[17,29] They may also report troublesome bruising or bleeding with sexual activity.

Menorrhagia is a fairly common manifestation of bleeding disorders, and the hemostatic cause can be von Willebrand disease, a platelet disorder, or a defect in coagulation or fibrinolysis.[7,16,17,29] However, menorrhagia can be due to other causes, such as fibroids.[3,18,29] Menorrhagia from inherited bleeding disorders is often long-standing, but it can be influenced by treatments. Accordingly, it is important to ask about menses when on, and not on, treatment. Menorrhagia can develop as a manifestation of an acquired bleeding problem (e.g., from acquired von Willebrand disease or anticoagulant therapy for deep vein thrombosis).

In general, it is more helpful to ask women quantitative or categorical questions about menses, rather than qualitative questions (e.g., are/were your menstrual periods heavy?). Questions to consider include the following: How many days of bleeding do you have with your typical menstrual periods? How many days of this bleeding was heavy flow? On your heavy days of flow, did you soak through sanitary products in an hour or less? What treatments have you taken for heavy periods? When you were not on treatment, how many days of bleeding (and how many days of heavy flow) did you have with a typical menstrual period? Were your periods like this when they first began, or did the heavy-flow problems start later in your life?

Menses up to 7 days in total duration, with 2 to 3 days of heavy flow, can be considered normal.[4,5,7,17,29] Although influenced by the absorbency of the products used, soaking through sanitary products in less than an hour is suspicious of menorrhagia, as is doubling up on products because of heavy flow and gushing and flooding accidents. Dysmenorrhea is common among women with bleeding disorders, and the passage of large blood clots (which reflect increased flow), which is typically painful, suggests the possibility of a bleeding disorder.[5] Pictorial bleeding-assessment tools (which are not applicable to an initial consultation visit) can be helpful to document menorrhagia and responses to treatment.[11,29]

Postpartum hemorrhage is rarely due to an underlying bleeding problem, and it can be complicated by a profound acquired coagulopathy, typically with severe fibrinogen depletion.[12-14] On the other hand, excessive or prolonged bleeding after childbirth or pregnancy loss can be problematic for some women with bleeding problems.[10,12] In addition, severe fibrinogen disorders and factor XIII deficiency compromise carrying a pregnancy to term and need to be excluded if the patient has unexplained pregnancy losses that are associated with hemorrhagic placental abruption[3] (see box on Case 4: Evaluation of an Isolated Symptom—Recurrent Pregnancy Loss With Bleeding).

During the first week after childbirth, the bleeding (lochia) is typically characterized by brighter red flow than a normal period. Afterward, the flow usually lightens and continues for up to 6 weeks postpartum. Flow can be heavier, or persist longer, in women with bleeding disorders.[10,12]

Anemia Related to Bleeding

A history of anemia and/or prior treatment with iron replacement is frequently reported by women with bleeding disorders.[3,17] Pallor of the palms is often observed when the hemoglobin is below 10 g/dL. Anemia is uncommon in individuals with bleeding disorders unless there is acute bleeding or chronic persistent bleeding leading to iron deficiency that compromises red cell production. Many women with bleeding disorders and menorrhagia have low iron stores, but not anemia. Low iron stores may also reflect ongoing gastrointestinal bleeding (overt or occult), which if present, requires investigation even if there is a known congenital or acquired bleeding problem. Some bleeding disorders (e.g., platelet disorders from GATA1 mutations) are associated with anemia and thrombocytopenia.

Joint Bleeds and Muscle Bleeds

Joint bleeds and bleeding into muscles (e.g., iliopsoas bleeds) are uncommon bleeding symptoms that suggest a severe coagulation defect or a fibrinolytic disorder.[1,3,6,7] However, bleeding into a joint after an injury or an orthopedic (e.g., arthroscopic) procedure can be experienced by persons with other types of bleeding disorders.[1,3,6,7] In patients with severe factor deficiencies, the clinical assessment should evaluate for symptoms and signs of arthropathy and muscle wasting and if relevant, neurologic sequelae complicating compartment syndrome bleeds.

Case 4: Evaluation of an Isolated Symptom—Recurrent Pregnancy Loss With Bleeding

A 32-year-old woman was referred for evaluation of a low fibrinogen level in the setting of an acute placental abruption, resulting in a third pregnancy loss (this time in the third trimester). She had no prior bleeding history apart from having suffered three placental abruptions associated with severe bleeding that required transfusion. The family history was negative for bleeding problems. She had previously been investigated for thrombophilia but had not been tested for a bleeding disorder. The low fibrinogen level persisted over many months (levels of approximately 90 mg/dL), suggesting that the defect was inherited. She received fibrinogen concentrate for two subsequent pregnancies, which she carried to term and delivered without bleeding problems. This case illustrates the need to consider inherited disorders when the bleeding symptoms are unusual and severe, even if there is only one bleeding symptom. It also illustrates that prognosis is dependent on diagnosis and treatment.

Subdural and Intracranial Hemorrhage

A newborn or child presenting with spontaneous intracranial hemorrhage or a large cephalohematoma should be investigated for severe underlying bleeding disorders, such as thrombocytopenia, hemophilia, factor XIII deficiency, other coagulation factor deficiencies, or a severe defect in platelets or von Willebrand factor.[1,3-5] Trauma-related subdural or intracranial hemorrhages can also be manifestations of a severe bleeding disorder.[1,3-5] In adults, thrombotic strokes are more frequent than hemorrhagic strokes, although hemorrhagic strokes appear to predominate with some bleeding disorders (e.g., Quebec platelet disorder[7]), and they can be complications of antithrombotic drug treatment.

Hematuria

Urinary tract bleeding with an infection is a commonly reported symptom, whereas spontaneous (or unexplained) hematuria can complicate hemophilia and other bleeding disorders, such as Quebec platelet disorder.[3,7,28]

Bleeding at Birth, Age-Related Changes in Bleeding, and Very Rare Bleeding Symptoms

Many individuals cannot answer questions about bleeding at the time that they were born. Nonetheless, bleeding from the umbilical stump or a cephalohematoma at birth can be symptoms of a bleeding disorder.[6,7] Menarche can cause a marked increase in bleeding in women with inherited or acquired bleeding problems. Some individuals with inherited bleeding disorders report a reduction in their bleeding symptoms as they age, which could reflect lifestyle adaptation and age-related increases in hemostatic protein levels (e.g., von Willebrand factor or fibrinogen) and thrombin generation. Increases in bleeding with aging can suggest an acquired problem (see box on Case 5: Illustration of Changes in Bleeding Problems Over Time).

Some types of bleeds are quite rare among individuals with bleeding disorders, including spontaneous hemorrhage into the spleen, which can lead to rupture (see box on Signs of Active or Recent Bleeding).

LABORATORY MANIFESTATIONS

The general investigations that are appropriate for most assessments of bleeding problems include (1) a complete blood count (to establish if there is thrombocytopenia or anemia), (2) an assessment for a low ferritin level to evaluate for iron deficiency (less commonly associated with microcytosis or anemia; deficit should be corrected if bleeding risks are increased), (3) a blood group and antibody screen, particularly for individuals with prior pregnancies or transfusions and upcoming surgery or major dental procedures, and (4) tests of renal function (creatinine) if antifibrinolytic therapy will be considered because the dosage is dependent on renal function or if an MYH9-related disorder is suspected (see box on The Laboratory Manifestations of Bleeding Disorders). The bleeding time test is no longer recommended, due to its technical limitations and poor sensitivity to common bleeding disorders.[3,16] Electrolyte levels merit monitoring when repeated doses of desmopressin therapy are given and/or if the fluid balance is difficult to assess. Tests of liver function are warranted if the person has risks for transfusion-acquired, chronic liver disease. Tests for liver and thyroid disease (particularly hypothyroidism) can be helpful if the history suggests an acquired bleeding problem of unknown etiology. Screening for Cushing syndrome (24-hour urine test for free cortisol) should be restricted to patients with acquired bleeding problems that suggest this possibility (e.g., bleeding associated with obesity, the development of type 2 diabetes, hypertension, striae, and/or changes in physical appearance).

Case 5: Illustration of Changes in Bleeding Problems Over Time

A 65-year-old woman presented for urgent evaluation of a bleeding problem, requiring treatment for a symptomatic, expanding subdural hematoma. She had been previously diagnosed with type 1 von Willebrand disease but indicated that she had no bleeding problems (despite many challenges) until she reached 30 years of age, when she began to experience increasing problems with bruising, menorrhagia, and challenge-related bleeding, including severe gum bleeds with routine dental cleaning. An activated partial thromboplastin time (aPTT) had been performed and was elevated. The testing confirmed a low level of factor VIII (14%) and a low level of ristocetin cofactor activity (less than 10%). The patient was given emergency treatment with plasma-derived von Willebrand factor concentrate containing factor VIII. Intravenous γ-globulin was given because she had a very poor response to replacement, suggesting rapid clearance of von Willebrand factor and factor VIII. Her von Willebrand factor and factor VIII levels increased above normal within 24 hours of the intravenous γ-globulin treatment, consistent with acquired von Willebrand disease. Additional tests indicated that she had an immunoglobulin G (IgG) paraprotein without evidence of myeloma. Several features of her presentation suggested that her von Willebrand disease was probably acquired and not due to type 1 von Willebrand disease (which is more common): her increasing bleeding symptoms over time and lack of bleeding problems during childhood or early adulthood, her very low level of factor VIII (due to its clearance with von Willebrand factor), the IgG paraprotein, her poor response to von Willebrand factor replacement, and her excellent response to intravenous γ-globulin. She has since been managed with intermittent intravenous γ-globulin treatment.

Signs of Active or Recent Bleeding and Conditions Associated With Bleeding

Although findings from the physical examination in bleeding disorders are often normal, it is important to look for signs of active or recent bleeding, including the following:

1. Petechiae, perifollicular hemorrhages (typical of scurvy)
2. Oral blood blisters, particularly if the patient has thrombocytopenia
3. Ecchymoses, hematomas, and skin pigmentation changes due to recurrent bleeds
4. Signs of active bleeding from a site of trauma or an incision, including excessive blood loss into drains
5. Sequelae of previous bleeds in individuals known or suspected to have a severe bleeding disorder, such as muscle wasting and arthropathy, neurologic abnormalities from prior intracranial or compartment syndrome bleeds
6. Pallor due to anemia: the palms are usually notably pale when the hemoglobin is less than 10 g/dL
7. Signs of an underlying hematologic disorder, such as lymphadenopathy and/or splenomegaly
8. Signs of acute or chronic liver disease, such as jaundice, hepatomegaly, spider nevi, palmar erythema, or Dupuytren contractures
9. Signs of an endocrine disorder, such as hypothyroidism or Cushing syndrome
10. Vascular lesions such as telangiectasia on the face or buccal mucosa, which can suggest hereditary hemorrhagic telangiectasia
11. Hyperextensibility if the bleeding history suggests Ehlers-Danlos syndrome as a potential diagnosis
12. Signs that suggest a syndromic bleeding disorder (albinism, hearing impairment, absent radii)

The Laboratory Manifestations of Bleeding Disorders

The laboratory manifestations of bleeding disorders can include abnormalities from the following:

1. The underlying hemostatic defect
2. Bleeding complications (e.g., anemia, iron deficiency, a coagulopathy of hemodilution after resuscitation for a massive bleed, development of red cell antibodies after transfusion)
3. False-positive abnormalities (e.g., prolonged activated partial thromboplastin time [aPTT] due to an incidental mild factor XII deficiency that occurs in about 1 of 200 patients or a lupus anticoagulant, which can be a transient finding in about 5% of ill, hospitalized patients)
4. Extremes of normal variation (e.g., mildly low von Willebrand factor levels in an individual who is blood group O, absent secondary aggregation with epinephrine in adjusted platelet rich–plasma aggregation studies).

The investigations for a bleeding problem typically also include screening tests (prothrombin time, activated partial thromboplastin time [aPTT], thrombin clotting time, and fibrinogen level), which are inexpensive tests, that detect acquired coagulopathies much more commonly than they detect inherited bleeding disorders because of differences in prevalence. These investigations are useful as a baseline for individuals at risk for developing a dilutional coagulopathy from bleeding and as initial investigations of a possible inherited or acquired coagulation disorder. Abnormalities, if detected, require further evaluation to determine if the cause is a fibrinogen disorder or a deficiency of one or more coagulation factors. Screening tests for von Willebrand disease are warranted for individuals with a personal or familial history of mucocutaneous bleeding.[10] Platelet function disorders should be evaluated by aggregation tests and tests for dense granule release, if available, because these tests are useful for assessing common bleeding disorders.[20,30] Chapters 131 and 132 provides more detail on the specific diagnostic tests that are appropriate for a laboratory workup of bleeding problems.

DIFFERENTIAL DIAGNOSIS OF BRUISING AND BLEEDING

The initial differential diagnosis should focus on three major categories (Table 130-1): deciding whether there is (1) no bleeding disorder, (2) a possible bleeding disorder (equivocal bleeding history and nondiagnostic laboratory findings), or (3) a definite bleeding disorder.

There are many potential inherited and acquired causes of definite bleeding problems (summarized in Tables 130-2 and 130-3). The history should be evaluated to determine if the problems suggest a defect in the initial control of bleeding (e.g., defects in platelet adhesion from von Willebrand disease or a platelet problem) or if there are delayed bleeding problems that suggest a defect in a coagulation factor or a fibrinolytic protein. Laboratory findings are important for distinguishing undefined bleeding problems from von Willebrand disease and platelet function disorders, because their symptoms are quite similar.[1,3,19,20,30]

Acquired bleeding problems due to drugs are often diagnosed solely by the medical history (i.e., acquired bleeding problems that occurred while taking a medication that inhibits coagulation or platelet function), although laboratory testing can be useful to rule out other causes. The subject's medical history and laboratory findings are helpful to determining if there is a possibility of acquired bleeding problems from a bone marrow disorder, liver disease, renal failure, or an endocrine disorder (e.g., hypothyroidism or, less commonly, Cushing syndrome)

Table 130-1 Differential Diagnosis of Bleeding Problems

Major Categories	Comments
No bleeding disorder	Symptoms do not reflect a bleeding disorder and have another explanation (e.g., a surgical bleed, not due to a bleeding disorder).
Possible bleeding disorder	The laboratory findings are nondiagnostic, and the bleeding history is considered equivocal (e.g., unexplained serious bleed with one surgical procedure; unexplained menorrhagia without other bleeding problems).
Definite bleeding disorder, undefined or indeterminate type	The bleeding history is consistent with a bleeding disorder; however, the laboratory findings are nondiagnostic. Commonly the bleeding history resembles mild to moderate defects in platelet function or von Willebrand factor. The diagnosis should only be made once an adequate evaluation for common bleeding disorders (e.g., for von Willebrand disease and platelet aggregation and release defects) is completed. If testing is not complete, the classification should indicate the types of conditions excluded or not excluded, for example: mild mucocutaneous bleeding problem, von Willebrand disease excluded, mild mucocutaneous bleeding problem, platelet release defects not yet excluded.
Definite bleeding disorder with a defined cause	The symptoms and laboratory findings are considered diagnostic of a bleeding disorder. Tables 130-2 and 130-3 summarize many of the potential inherited and acquired causes.

PROGNOSIS

The prognosis for bleeding problems depends on the severity of the nature of the hemostatic defect, exacerbating factors, and whether these problems can be readily corrected (e.g., vitamin K to correct a deficiency, discontinuing aspirin) or if they require hemostatic therapies, such as factor concentrates and/or drugs (e.g., desmopressin, tranexamic acid, or aminocaproic acid). Life expectancy is generally normal unless there is a severe bleeding disorder (e.g., severe hemophilia) or a complication (e.g., transfusion-acquired chronic hepatitis or human immunodeficiency virus [HIV]). The prognosis for some rare disorders significantly improves after puberty (e.g., factor IX Leyden). A few show progressive worsening over time (e.g., development of aplasia from congenital amegakaryocytic thrombocytopenia, transformation of thrombocytopenia from an inherited RUNX1 mutation into myelodysplasia or acute myeloid leukemia). Other disorders (e.g., acquired hemophilia) may go into complete remission after immunosuppressive treatment with risk for later relapses.

Mild platelet function disorders, mild type 1 von Willebrand disease, and many common undefined conditions that cause mucocutaneous bleeding usually respond sufficiently well to prophylactic desmopressin therapy, which is given to prevent bleeding with major surgical and dental procedures or bleeding with childbirth. Nonetheless, it is important to have a specific diagnosis to manage situations in which desmopressin therapy is insufficient to control bleeding.

Women with bleeding disorders have a similar prognosis to men, although they often have a greater burden of symptoms due to menorrhagia and childbirth-related bleeding.[1,3] Their outcomes with pregnancy and childbirth are often similar to individuals without bleeding disorders provided that they receive treatment to control bleeding with delivery.[1,3] However, some disorders have sufficiently good outcomes with childbirth that treatment for uncomplicated childbirth is not required (e.g., for Quebec platelet disorder).[7,28] Childbirth plans for women with bleeding disorders requires consideration of the

Table 130-2 Differential Diagnosis of Congenital Bleeding Disorders

Disorder	Comments
Fibrinogen deficiency or dysfunction	Deficiencies can be mild-moderate hypofibrinogenemia or severe afibrinogenemia. Fibrinogen function is abnormal in dysfibrinogenemias, which can present with bleeding, thrombosis, or both. Fibrinogen levels can be reduced in some dysfibrinogenemias.
X-linked coagulation factor deficiencies—hemophilia	Presentation is influenced by the degree of deficiency. Factor VIII deficiency is more common than factor IX deficiency. If factor VIII is low, von Willebrand disease needs to be excluded as the cause.
Rarer, coagulation factor deficiencies	Deficiencies can affect factors XI, V, II, VII, or X, and the presentation is dependent on the severity of the deficiency. Hereditary deficiencies of multiple coagulation factors are rare (e.g., of factors V and VIII, or multiple vitamin K–dependent coagulation factors for congenital defects impairing γ-carboxylation) and can easily be excluded by measuring multiple factors.
Fibrinolytic defects	Causes include disorders caused by loss of function, such as α_2-antiplasmin or PAI-1 deficiency, and by gain-of-function defects, such as Quebec platelet disorder (overexpression of urokinase plasminogen activator in megakaryocytes).
von Willebrand disease	Causes include quantitative (partial type 1 to severe type 3) and qualitative defects (loss of function in type 2M and 2A, gain of function in type 2B and platelet-type). Type 1 von Willebrand disease can be confused with low von Willebrand factor levels (e.g., due to blood group O).
Platelet disorders	These conditions can affect platelet number, function, or both. The most common type of platelet function disorder is a platelet secretion defect, which may or may not also impair aggregation responses. Disorders of platelet function are commonly subclassified by the nature of the defect, such as the following: 1. Defects of membrane receptors for adhesive proteins (e.g., Glanzmann thrombasthenia and Bernard-Soulier syndrome) or agonists (e.g., $P2Y_{12}$ deficiency) 2. Defects of signaling or secretion (the largest subcategory) 3. Cytoskeletal defects (e.g., MYH9-related disorders) 4. Storage pool disorders (e.g., gray platelet syndrome, dense granule deficiency, αγ-storage pool deficiency, Quebec platelet disorder) 5. Defects of procoagulant function (e.g., Scott syndrome)
Vascular disorders	Congenital vascular malformation, including hereditary hemorrhagic telangiectasia, Ehlers-Danlos syndrome

options for pain management and avoidance of procedures, such as spinal or epidural anesthesia, to limit bleeding risks unless the defect can be readily corrected.

THERAPY

An individual's bleeding history is an important consideration whenever formulating therapeutic plans to control and minimize bleeding risks. Some symptoms do not warrant therapy (e.g., bruising), whereas treatment is important for controlling menorrhagia and for preventing and limiting challenge-related bleeding (e.g., from major or minor surgery and dental procedures, and traumas). For severe disorders, prophylactic treatment is warranted to prevent spontaneous bleeding and to limit challenge-related bleeding, which can be severe. The focus of therapy for some acquired conditions (e.g., acquired hemophilia) is immunosuppressive therapy to achieve a remission while managing any acute bleeding that warrants therapy. For individuals with mild bleeding disorders, who have undergone multiple prior surgical procedures without bleeding, it may be appropriate to have treatment available (e.g., desmopressin on "standby") that is to be administered if and when abnormal bleeding occurs, provided that the procedural-related risks of bleeding are small and readily managed (e.g., biopsy under local anaesthetic) while waiting for the medication to have an effect.

For women with bleeding disorders, there are general treatments that can be considered for symptomatic management regardless of the type of bleeding disorder. For example, options for menorrhagia management include oral contraceptives, antifibrinolytic drugs, and hormone-releasing intrauterine devices. When menorrhagia limits lifestyle and further pregnancies are not desired, surgical options (endometrial ablation, hysterectomy) may be preferred options, particularly when menopause is not imminent.

General management of bleeding often includes supportive care, correction and prevention of anemia (e.g., iron replacement for iron deficiency), and immunization against viruses that may be acquired by blood transfusion (e.g., hepatitis A and B) (see box on Case 6: Illustration of Changes in Bleeding Outcomes With Treatment). If the patient is immobilized or is undergoing a procedure with significant risks for thrombosis, there should be plans for anticoagulant therapy if the defect can be corrected during this treatment (e.g., by factor replacement therapy for hemophilia or von Willebrand disease, fibrinolytic inhibitor therapy for Quebec platelet disorder) or for alternative thromboprophylaxis if this is not possible (e.g., use of venous compression devices without anticoagulant drugs if the treatment will provide only brief hemostatic correction [e.g., desmopressin, platelet transfusions]). Other measures to limit bleeding risks from bleeding disorders, with surgery, include the avoidance of intramuscular injections, spinal and epidural anesthesia, and NSAIDs for pain management. In older individuals with bleeding disorders and symptomatic atherosclerotic disease (e.g., angina), aspirin therapy may be appropriate, with increased vigilance for signs and symptoms of significant bleeding.

For more information on therapies for specific disorders, see the chapters on hemophilia (Chapters 137 and 138), rare coagulation factor deficiencies (Chapter 139), von Willebrand factor (Chapter 140), and platelet disorders (Chapter 132).

FUTURE DIRECTIONS

The development of a bleeding-assessment tool with sufficient utility to distinguish persons with bleeding disorders from those without significant bleeding problems could improve the clinical assessment of bleeding disorders. There is a need for more information on the genetic causes of common disorders (e.g., type 1 von Willebrand disease, common platelet function disorders such as secretion defects) to further understand bleeding disorder pathogenesis and bleeding risks.

Table 130-3 Differential Diagnosis of Acquired Bleeding Problems

Disorder	Comments
Drug induced	Aspirin, NSAIDs, other platelet function inhibitors (e.g., $P2Y_{12}$ and $\alpha_{IIb}\beta_3$ inhibitors), anticoagulants, fibrinolytic drugs, and antidepressants are common causes
Acquired factor deficiencies	The causes can be immune (e.g., acquired factor VIII deficiency, acquired factor V deficiency) or nonimmune. Reductions in multiple factors can result from vitamin K deficiency, treatment with vitamin K antagonists, liver disease, hemodilution, and rarely snakebites. Severe acquired hypofibrinogenemia is commonly due to a postpartum coagulopathy or severe liver disease. Prothrombin deficiency occurs with some lupus anticoagulants. Amyloidosis can cause an acquired factor X deficiency, which may be associated with reductions in other coagulation factors synthesized in the liver if the liver is involved.
Disseminated intravascular coagulation	The manifestations can include thrombocytopenia, consumption of coagulation factors, including fibrinogen, and impairment of hemostatic mechanisms from the fibrin/fibrinogen degradation products. Causes are wide ranging and include postpartum consumptive states, prostate and other cancers, and snakebites.
Acquired von Willebrand disease	The cause can be immune (often in association with an IgG paraprotein) or nonimmune (e.g., increased proteolysis of von Willebrand factor with stenotic aortic valvular disease).
Immune thrombocytopenia	Bleeding is usually influenced by the extent of the thrombocytopenia. Some autoantibodies interfere with platelet membrane receptor function, causing bleeding disproportionate to the thrombocytopenia.
Non–drug induced, acquired platelet function disorders	The cause can be immune (see earlier) or nonimmune, typically from bone marrow disorders, although secretion defects can be secondary to Cushing syndrome or hypothyroidism.
Liver disease	Liver disease can cause thrombocytopenia, deficiencies of coagulation factors, hypofibrinogenemia and dysfibrinogenemia, and increased fibrinolysis. In mild liver disease, factor VII and sometimes factors XI and XII are low. Fibrinogen is often increased in early liver disease, and if low, the finding suggests severe liver disease.
Renal disease	Anemia is an important predictor of uremic bleeding. Uremic bleeding is typically associated with severe renal impairment.
Hypothyroidism	Hypothyroidism can cause an acquired von Willebrand disease and acquired defects in platelet function.
Cushing syndrome	This syndrome should be suspected when there are symptoms and findings suggestive of Cushing syndrome or treatment with systemic or topical glucocorticoids.
Surgical bleeding	This is often a diagnosis of exclusion, although the procedural notes sometimes document that a technical problem was encountered that led to abnormal bleeding.
Vitamin K deficiency	Newborns are at risk, as are individuals with malabsorption and/or receiving broad-spectrum antibiotics that reduce vitamin K production by reducing gut bacteria. Older adults are also at greater risk for developing vitamin K deficiency, due to reduced stores from poorer intake of vitamin K. If the patient does not respond to parenteral vitamin K, other causes should be considered.
Vitamin C deficiency (scurvy)	This diagnosis should be considered when there is lethargy with skin and gum bleeding (perifollicular hemorrhages, gum bleeding with swelling). The condition is rare in developed countries. The cause is usually a very poor diet or malabsorption.

IgG, Immunoglobulin G; *NSAID,* nonsteroidal antiinflammatory drug.

Case 6: Illustration of Changes in Bleeding Outcomes With Treatment

A 38-year-old woman was evaluated for a bleeding disorder. Her family physician had already excluded the possibility of von Willebrand disease. The patient had a long-standing history of massive bruises, often without recollection of trauma, prolonged nosebleeds requiring medical attention since early childhood, prolonged bleeding from minor cuts, and severe bleeding requiring blood transfusions with many surgical procedures. She had a history of recurrent iron deficiency anemia, menorrhagia requiring medical therapies, and immediate postpartum bleeding. Her father had a history of bleeding problems, but the cause of the bleeding problem in the family was unknown. The history suggested an inherited disorder, possibly a platelet function disorder or a form of von Willebrand disease. The testing indicated that she had a platelet secretion defect with multiple aggregation abnormalities, with no evidence of von Willebrand disease. She underwent additional surgical procedures, using desmopressin treatment to reduce her bleeding risks, with no abnormal bleeding. Her menorrhagia was controlled with tranexamic treatment. She self-administered desmopressin treatment to control nosebleeds, with good effect. This case illustrates that treatment affects bleeding outcomes and the importance of evaluating for common defects in hemostasis.

CHAPTER 131

LABORATORY EVALUATION OF HEMOSTATIC AND THROMBOTIC DISORDERS

Alvin H. Schmaier

The clinical laboratory evaluation is an integral part of the diagnosis and management of patients with hemostatic/thrombotic disorders. A clinical hematologist when challenged by patients with hemostatic/thrombotic disorders is as good as the laboratory that serves him or her for diagnosis and management. This chapter provides a critical practical approach to the diagnosis and management of bleeding and clotting disorders. The latter activity is a new use of laboratory resources for what until the present era has mostly been a diagnostic facility.

Physiologic hemostasis is the sum of protein (coagulation, fibrinolytic, and anticoagulation) and cellular (platelets, endothelial cells, and leukocytes) elements working in concert to staunch the bleeding at sites of vascular injury without occlusive thrombosis. There is no one assay for hemostatic integrity. For example, a patient with Glanzmann thrombasthenia has abnormal platelet function but normal blood coagulation studies. Another patient with factor VIII deficiency has prolonged surface-activated blood coagulation tests, but normal platelet function. Both patients are hemostatically incompetent. The cellular elements, platelets, endothelial cell, and leukocytes localize physiologic hemostasis and provide proteins and peptides that contribute to the process. The proteins of the blood coagulation system lead to thrombin formation. The role of the fibrinolytic system is to lyse clots formed by thrombin. The role of the anticoagulation system is to regulate all the enzymes of the coagulation and fibrinolytic systems so that no excess clotting or bleeding occurs. The sum of these elements leads to the hemostatic plug (Fig. 131-1). Thus the present approach to patients with bleeding disorders is to evaluate the plasma proteins of the hemostatic, fibrinolytic, and anticoagulation systems and platelet number and function that contribute to this process.

For decades the proteins of the hemostatic system have been referred to as the "coagulation cascade" based on the waterfall hypothesis of Ratnoff and Davies[1] and MacFarland,[2] who almost simultaneously reported a sequence of proteolytic reactions starting with factor XII (Hageman factor) activation and ending with formed thrombin proteolyzing fibrinogen to form a clot. However, upon introduction, this hypothesis for physiologic hemostasis was untenable because it was known that factor XII deficiency is not associated with bleeding.[3] By the mid-1970s, the cofactors for factor XII activation (prekallikrein and high-molecular-weight kininogen) were identified, and deficiencies of these proteins also were not associated with a bleeding state.[4-6] In 1977, Osterud and Rappaport[7] recognized that factor VIIa is able to activate factor IX to factor IXa. Later Broze[8] recognized that the kinetics of tissue factor pathway inhibitor (TFPI) were such that, under physiologic circumstances, the factor VIIa/tissue factor complex cannot directly activate factor X, because of the presence of TFPI, but must go through factor IX activation. If this is the case, how does factor XI, whose deficiency is associated with bleeding, become activated independent of factor XIIa? In 1991, Gailani and Broze[9] proposed that formed thrombin cycles back to activate factor XI, resulting in amplification of activation of thrombin formation. Presently, physiologic hemostasis is believed to be an interacting system initiated by factor VIIa and tissue factor activation and amplification of several zymogens that become serine proteases (Fig. 131-2; see Chapter 128). Although the material just presented has become a cohesive hypothesis for physiologic coagulation activation, clinical laboratory testing of the proteins of coagulation is not based on this current understanding—it follows the Ratnoff and Davies hypothesis.

The clinical laboratory assays used to examine the proteins of the coagulation system are based on the original surface-activated coagulation cascade hypothesis.[1,2] Although these tests do not represent physiologic hemostasis, they are useful for diagnosis of defects in coagulation proteins and potential bleeding disorders. Thus the clinician must understand the distinction between physiologic coagulation, fibrinolysis, and anticoagulation contributing to hemostasis and the diagnostic tests that are used to measure these systems. The first part of this chapter describes the assays used to measure blood coagulation–protein bleeding disorders. Understanding these assays is an approach to recognizing a potential bleeding abnormality in a patient. In addition to diagnosis of a bleeding disorder, the coagulation laboratory has the potential to assist the physician in patient management by monitoring changes in the degree of activated blood coagulation.

When faced with a bleeding patient, the hematologist must use an analytic diagnostic approach to determine the cause of the bleeding. Most recognized bleeding states are caused by one of three defects: a defect or deficiency in a plasma protein, a defect in platelet number or function, or a defect in platelet–vessel wall interactions (i.e., an abnormality in the adhesive interactions between platelets and the vessel wall), as in defects associated with the presence or function of von Willebrand factor. Collagen and platelet glycoprotein VI (GPVI) also participate in adhesive interactions, but GPVI deficiency is not a hemostatic disorder.

When approaching the diagnosis of a coagulation protein defect in a patient, understanding the mechanism is paramount. Any coagulation protein defect can be a true protein deficiency, an abnormal protein that cannot participate in its physiologic function(s), or an inhibitor directed against the active site of the protein or one that induces enhanced clearance of the protein. In general, inhibitors to a coagulation protein are immunoglobulins, although abnormal production of endogenous heparin, fibronectin, or cryoglobulins has been reported as the source of acquired inhibitors to coagulation proteins.[10] An abnormal coagulation protein can result from missense, deletion, or translocations of its deoxyribonucleic acid (DNA). Last, enhanced clearance of coagulation proteins usually occurs as a result of an antibody-protein complex that is recognized as foreign and thus removed from the circulation.[11] The resultant increased clearance of the protein results in a deficiency of the protein. Thus clinical laboratory testing, when available, should focus on measuring the presence of the protein by antigen and its functionality by a variety of assays.

In general, hemarthrosis and spontaneous soft-tissue and intramuscular hemorrhage characterize defects of coagulation proteins, such as hemophilia A and B (factors VIII and IX deficiency). Soft-tissue petechiae, purpura, or ecchymoses characterize von Willebrand disease or platelet number or functional disorders. However, distinguishing the potential mechanism for bleeding can be difficult. History and physical examination are important components of the hemostatic workup (see Chapter 130) but are inadequate for specific diagnosis of bleeding or clotting disorders. Thus the clinical laboratory is essential for definitive diagnosis of a blood coagulation protein defect leading to bleeding.

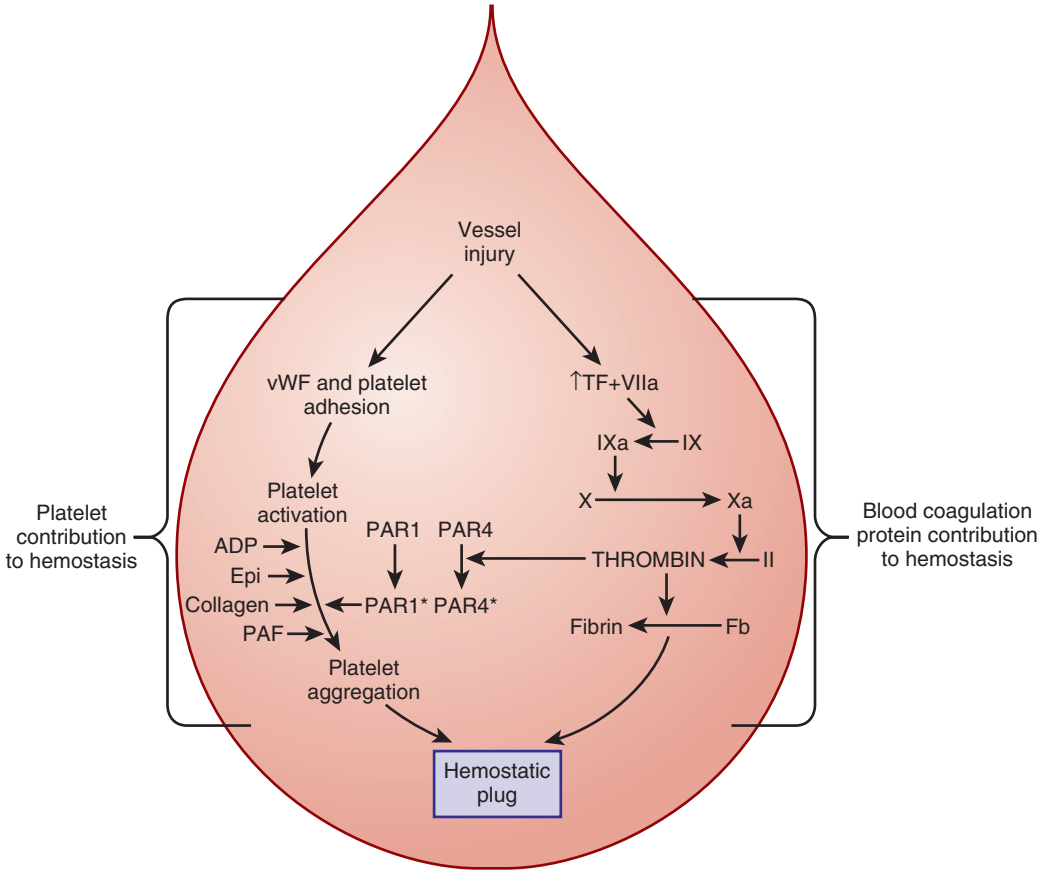

Figure 131-1 SCHEMATIC DIAGRAM OF HEMOSTASIS. Two equally important arms of activity contribute to physiologic hemostasis. The platelet contribution to hemostasis is as follows: When a vessel is injured, exposing collagen, platelets adhere to the injury site via von Willebrand factor (vWF) and, in high-shear areas, glycoprotein VI (not shown in figure). Upon adherence, the platelets are activated and release their granule contents. Released adenosine diphosphate (ADP) and other granule contents recruit more platelets to the injury site. Simultaneously at the site of injury, subendothelial cell tissue factor (TF) is upregulated and with activated factor VII (VIIa) activates factor IX to activated factor IX (IXa) and, sequentially, factor X to activated factor X (Xa) and prothrombin (II) to thrombin. Exposed collagen also allows for factor XII autoactivation and generation of additional thrombin in the milieu of activating platelets (not shown in figure). Thrombin stimulates more platelets, enhancing the platelet plug. Thrombin also proteolyzes fibrinogen to form fibrin monomer, which then polymerizes into a fibrin clot. These events occur on or about the activated platelet surface. *Epi,* Epinephrine; *Fb,* fibrinogen; *PAF,* platelet-activating factor; *PAR,* protease-activated receptor.

CLINICAL SCREENING ASSAYS IN HEMOSTATIC TESTING TO DETECT COAGULATION PROTEIN DEFECTS

In the practice of clinical hemostasis, there are no good global assays for measuring physiologic tissue factor–initiated hemostasis. The three assays most commonly used to examine the proteins of the blood coagulation system are (1) the activated partial thromboplastin time (aPTT) induced by surface (contact) activation of factor XII, (2) the prothrombin time (PT) induced by the addition of excess tissue factor, and (3) the thrombin clotting time (TCT), a test of fibrinogen integrity or inhibitors of the added thrombin. In the aPTT assay, surface or contact activation of the blood coagulation system occurs because factor XII associates with the reagent's negatively charged substances, such that the protein changes shape to allow its autoactivation and subsequent initiation of the cascade of proteolytic reactions seen in the coagulation system.[12-14] These phenomena are the basis of the Ratnoff and Davies hypothesis for activation of the coagulation system. This test measures more proteins (factor XII, prekallikrein, high-molecular-weight kininogen) than those necessary for physiologic hemostasis. In the PT assay, addition of excess tissue factor creates a nonphysiologic change in the normal stoichiometric relationship of coagulation factors, thereby allowing factor VIIa to overcome the inhibitory effect of TFPI and favoring direct activation of factor X to factor Xa without the usual physiologic requirement to proceed through factor IX activation. In the TCT assay, exogenous thrombin is added to examine the integrity of its major substrate, fibrinogen.

When all three assays are performed simultaneously on a sample of plasma, the results indicate almost all of the diagnostic categories for a blood coagulation protein bleeding state. It is most useful to perform a diagnostic evaluation at one time with a complete panel of assays rather than a series of piecemeal studies. The former approach provides a complete snapshot of the patient's blood coagulation parameters, which is best for diagnosis. Patient conditions usually are dynamic, so piecemeal evaluations often miss evolving clinical states. The three screening tests are performed as follows:

1. *Activated partial thromboplastin time.* To perform this assay, equal parts of a negatively charged surface and phospholipid mixture and patient plasma are incubated for more than 5 minutes. Calcium chloride is added to 30 mM to recalcify citrated plasma,

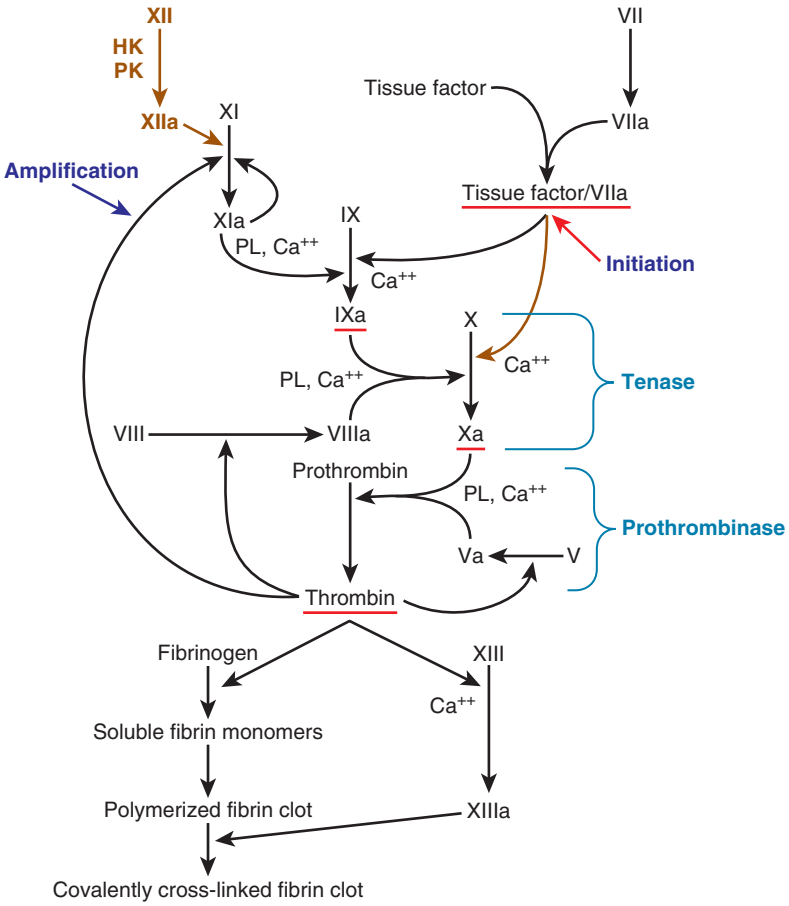

Figure 131-2 SCHEMATIC DIAGRAM OF PHYSIOLOGIC HEMOSTASIS. Formation of the tissue factor–activated factor VII complex (TF/VIIa) results in factor IX activation to activated factor IX (IXa). TF/VIIa does *not* normally activate factor X directly *(brown line)*. Activated factor IX activates factor X to activated factor X (Xa) in the presence of activated factor VIII (VIIIa), which must have been formed from some prior thrombin activation of factor VIII (tenase). Activated factor X in the presence of activated factor V (Va) activates prothrombin to thrombin (IIa) (prothrombinase). Thrombin proteolyzes fibrinogen to form a fibrin clot. If more thrombin is needed, thrombin can activate factor XI to activated factor XI (XIa), which then activates more factor IX to factor IXa, which makes more activated factor X and thrombin. If more thrombin-induced clot formation is needed, thrombin also activates carboxypeptidase U to form a thrombin-activatable fibrinolysis inhibitor (TAFI) that inhibits fibrinolysis (pathway not shown). Factor XI also can be activated by activated factor XII, which is formed secondarily by the constitutive activation of prekallikrein (PK) in the presence of high-molecular-weight kininogen (HK) by contact activation in collagen-exposed injured vessels. These latter mechanisms are *not* constitutive for physiologic hemostasis. However, in nonphysiologic states, such as sepsis, clot formation in the intravascular compartment, or cardiopulmonary bypass, activated factor XII can activate factor XI to initiate hemostasis with thrombin formation. This latter mechanism is the basis of the activated partial thromboplastin time, a major screening test for hemostatic disorders. *PL,* Phospholipid. *(Modified from Schmaier AH, Miller J: Coagulation and fibrinolysis. In McPherson RA, Pincus MR, editors:* Henry's clinical diagnosis and management by laboratory methods, *ed 22, Philadelphia, 2011, Elsevier, p 785.)*

and the time required for clot formation is measured. The aPTT assay assesses the coagulation proteins of the intrinsic and common pathways (Fig. 131-3).[15]

2. *Prothrombin time.* To perform this assay, tissue thromboplastin (tissue-derived or recombinant human tissue factor), phospholipid, and patient plasma are incubated for more than 5 minutes. The plasma then is recalcified by the addition of calcium chloride to 30 mM, and the time required for clot formation is measured. The PT assay assesses the coagulation proteins of the extrinsic and common pathways (see Fig. 131-3).[16] The sensitivity of the assay is based on similarity of the tissue factor used in the assay to human tissue factor (see Interpretation of Screening Tests of the Coagulation System).
3. *Thrombin clotting time.* To perform this assay, purified thrombin is added to plasma, and the time to clot formation is measured. It is a direct measure of the conversion of fibrinogen to fibrin (see Fig. 131-3). When performing this assay, it is essential to use the minimal amount of α-thrombin (3000 units/mg specific activity)

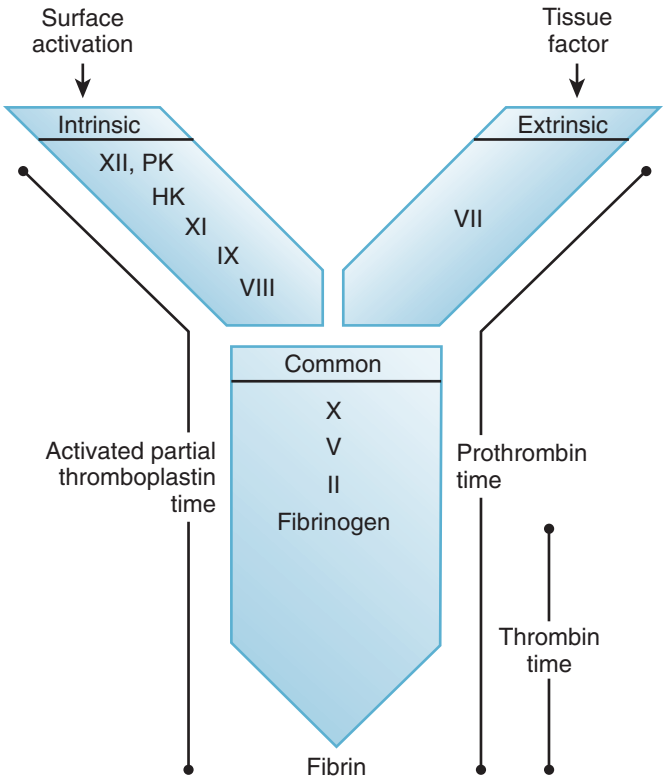

Figure 131-3 ORGANIZATION OF THE COAGULATION SYSTEM BASED ON CURRENT SCREENING ASSAYS. The intrinsic coagulation system consists of the protein factors XII, XI, IX, and VIII and prekallikrein (PK) and high-molecular-weight kininogen (HK). The extrinsic coagulation system consists of tissue factor and factor VII. The common pathway of the coagulation system consists of factors X, V, and II and fibrinogen (I). The activated partial thromboplastin time requires the presence of every protein except tissue factor and factor VII. The prothrombin time requires factors VII, X, V, and II, and fibrinogen. The thrombin clotting time only tests the integrity of fibrinogen. *(Modified from Schmaier AH:* Approach to the bleeding patient. *In Schmaier AH, Petruzzelli LM, editors:* Hematology for the medical student, *Philadelphia, 2003, Lippincott Williams & Wilkins, p 79.)*

that will reproducibly "clot" fibrinogen, usually 2 to 6 units/mL, aiming for approximately 20 seconds with pooled normal plasma to achieve maximal sensitivity for a clinically useful assay.[17,18] This assay is distinguished from the clottable fibrinogen assay (Clauss assay) by the amount of thrombin used (50 units/mL in the Clauss assay).[19]

The results of these assays allow the 40-year-old cascade hypothesis to guide the clinician to a practical differential diagnosis of what protein(s) may be affected. In the coagulation cascade hypothesis, coagulation proteins are classified as members of the intrinsic system, the extrinsic system, or the common pathway (see Fig. 131-3).

All coagulation assays examine the rate of clot formation. In these assays, a sequence of proteolytic reactions takes place, leading to thrombin formation and its proteolysis of fibrinogen. Proteolysis of fibrinogen results in clot formation with precipitation of soluble proteins that are detected by either increased impedance or turbidity or decreased optical clarity, based on the instrumentation used to measure the result. Any defect along the pathway to clot formation will give an abnormal (i.e., a delayed time) result. Furthermore, because a series of reactions must occur to result in the final clot formation, any substance (e.g., inhibitory antibodies, heparinoids, anticoagulants) that interferes with the assay downstream from a specific factor's activity will lead to an abnormal result. For example, a potent inhibitor to factor VIII will give an abnormal factor XI or IX coagulant assay. Likewise, a deficiency of fibrinogen or an abnormal fibrinogen will affect the results of the aPTT and PT assays even though the levels and function of all the upstream coagulation factors are normal.

INTERPRETATION OF SCREENING TESTS OF THE COAGULATION SYSTEM

When diagnosing potential bleeding disorders, the coagulation cascade hypothesis and its grouping of coagulation proteins are used to interpret the screening tests for various deficiencies or abnormalities in the coagulation proteins (see Fig. 131-3).

The in vitro event of factor XII autoactivation in the aPTT assay initiates the sequence of reactions of the coagulation cascade.[1,2] The aPTT assay measures all the proteins of the intrinsic system (factor XII, prekallikrein, high-molecular-weight kininogen, factor XI, factor IX, and factor VIII) and the proteins of the common pathway (factors X, V, II, and fibrinogen). It is important to realize that the coagulation proteins need to decrease to different levels before the various screening assays show an abnormality. For example, most commercial aPTT reagents detect a decrease in factor VIII when the protein level decreases to 35% to 45% of normal (i.e., 0.35 to 0.45 units/mL). Alternatively, factor XII and high-molecular-weight kininogen at levels of 10% to 15% of normal will only just begin to show abnormalities on the aPTT assay.[20,21] Similarly, factor VII levels below 35% to 40% will be detected on the PT assay. The sensitivity of the screening tests for detection of specific abnormalities varies with the factor being tested, the commercial reagent used in the assay, and the equipment platform for measurement. Each clinical laboratory should know the level of decrease for each coagulation factor that produces an abnormal aPTT or PT with their current equipment and reagents.[22]

The PT assay measures the extrinsic pathway of coagulation, which consists of activated factor VII (factor VIIa) and the proteins of the common pathway (factors X, V, II, and fibrinogen).[16] The PT assay also is used to monitor warfarin therapy.[23,24] In this capacity, the test reporting has been modified so that it can be interpreted universally. Because of the plethora of commercially available PT reagents and coagulation instruments, it is impossible for physicians to know normal values for the PT from any given laboratory. A convention called the international normalized ratio (INR) was developed to standardize the reporting of PT for patients taking warfarin.[23] $INR = (\text{patient's PT/mean laboratory control PT})^{ISI}$, where ISI (international sensitivity index) for a reagent is a measure of the responsiveness of a given thromboplastin to reduction of the vitamin K–dependent coagulation factors. The reliability of the PT decreases as the ISI of the thromboplastin reagent increases and the therapeutic range for the PT diminishes.[24] The ISI is provided by each manufacturer based on the degree of variation of the thromboplastin from the World Health Organization (WHO) reference thromboplastin that has an arbitrarily assigned value of 1. The orthogonal regression slope of the calibration line for any thromboplastin is determined by z, the logarithm of a PT per second determined with the WHO standard, and x, the logarithm of PT in seconds determined with the test preparation, according to the equation $z = a_1 + b_1x$, where $b_1 = m +$ square root of $m^2 + 1$ and $a_1 = z - b_1x$ (see Pollar[24] for meaning of m in these equations). Manufacturer determination of ISI requires a minimum of 20 normal donors and 60 samples of patients stable on warfarin therapy with INRs from 1.5 to 5.0.[24] The higher the ISI, the less sensitive the thromboplastin. Human recombinant thromboplastin gives an ISI value of approximately 1.0. In practice, the term *INR* has become common parlance to describe all PT changes from normal. In reality, it should be used only to characterize the degree of PT prolongation of a plasma sample from a patient on warfarin.

TCT only measures the ability of exogenous thrombin to proteolyze (clot) fibrinogen. It only assesses fibrinopeptide A and B release

Table 131-1 Laboratory Evaluation of Abnormalities of Coagulation Protein aPTT and PT Screening Tests

Long aPTT, Normal PT	Long PT, Normal aPTT	Long aPTT and PT
ASSOCIATED WITH BLEEDING		**THINK MEDICAL STATES (COMMON)**
Factor VIII (male only)	Factor VII (rare)	
Factor IX (male only)	†Slight defects in factors XI, X, II, V and dysfibrinogenemias	Anticoagulants
		DIC
Acquired inhibitors to factor VIII		Liver disease
Amyloid adsorbed factor IX		Vitamin K deficiency
		Massive transfusion
Factor XI		
NOT ASSOCIATED WITH BLEEDING		Antibodies to factor V
Factor XII	**SINGLE FACTOR DEFICIENT**	
Prekallikrein	Perform specific inhibitor assay	**COMMON PATHWAY**
High-molecular-weight kininogen		**DEFICIENCIES (RARE)**
Lupus anticoagulant		Factors X, V, II
		Dysfibrinogenemias
SINGLE FACTOR DEFICIENT		
Perform specific inhibitor assay		**SINGLE FACTOR DEFICIENT**
		Perform specific inhibitor assays
MULTIPLE FACTORS DEFICIENT		
Pan-inhibitor* (e.g., lupus anticoagulant, immunoglobulin)		**MULTIPLE FACTORS DEFICIENT** Pan-inhibitors

aPTT, Activated partial thromboplastin time; *DIC,* disseminated intravascular coagulation; *ISI,* international sensitivity index; *PT,* prothrombin time.
*Pan-inhibitor: general description of a nonspecific inhibitor that can be an immunoglobulin (e.g., lupus anticoagulant, myeloma protein) or natural substance (heparin, fibronectin, amyloid) that binds coagulation proteins and interferes with their function.
†This occurs with more sensitive PT reagents, ISI ≈1.0.

from fibrinogen and fibrin polymerization. A prolonged TCT, as indicated by values outside the 95% confidence interval for the time to clot of a population of 20 or more normal donors, suggests reduced fibrinogen levels (usually <100 mg/dL), abnormal fibrinogen function, or the presence of an inhibitor of thrombin.

Knowing what each test measures, the clinician can use the following approach to evaluate bleeding risk in patients who have prolonged values in one or more of these assays (Table 131-1). For example, if a patient has an isolated prolonged aPTT, determination of the patient's risk to bleed begins with the addition of historical information (see Chapter 130). If isolated prolongation of the aPTT is associated with bleeding, then the differential diagnosis in decreasing likelihood of frequency is factor VIII, factor IX, or factor XI deficiency. Factor VIII and IX deficiencies are sex linked and usually are seen only in males; factor XI deficiency is autosomal recessive and is seen in males and females (see Chapters 137 and 139 for a full discussion). If the aPTT alone is prolonged and the patient has no history of bleeding, the most common cause is a lupus anticoagulant (see Chapter 143). The specific proteins of the intrinsic coagulation system associated with a prolonged aPTT but no bleeding history in decreasing frequency are factor XII, prekallikrein, and high-molecular-weight kininogen deficiency (Table 131-2). All of these defects are autosomal recessive and rare. Knowing about these latter three proteins is essential to evaluating a prolonged aPTT, even though the patient is not at bleeding risk. It also is important to recognize these protein defects so that patients do not undergo unnecessary plasma replacement therapy. Information indicates that factor XII and high-molecular-weight kininogen contribute to the extent of thrombosis independent of hemostasis.[25,26] In flowing blood under high shear with collagen exposure, factor XII autoactivation contributes to the extent of fibrin/platelet clot formation.[25,27,28] Thus factor XII influences thrombosis risk but not hemostasis.

Table 131-2 Clinical Peculiarities of Coagulation Protein Screening Tests

Long aPTT, Normal or Long PT, No Bleeding	Normal aPTT, PT, With Bleeding
LONG APTT ONLY	
Factor XII deficiency	Factor XIII deficiency or inhibitor
Prekallikrein deficiency	α_2-Antiplasmin deficiency or defect
High-molecular-weight kininogen	Plasminogen activator inhibitor deficiency or defects
Lupus anticoagulant	α_1-Antitrypsin Pittsburgh defect
LONG APTT AND PT	
Dysfibrinogenemia with fibrinopeptide B–release defect Lupus anticoagulant	

aPTT, Activated partial thromboplastin time; *PT,* prothrombin time.

Individuals can have acquired disorders that inhibit specific coagulation factors and increase their risk for bleeding. The clinical laboratory phenotype of these patients depends on the protein to which the coagulation protein inhibitor is directed. The most common severe acquired coagulation protein inhibitor is a spontaneous antibody inhibitor to factor VIII that is seen in both males and females (see Chapters 137 and 138). Patients with the disorder present with bleeding and a long aPTT. Characteristically this inhibitor is seen in older adult patients, patients with B-cell malignancies, patients with

connective tissue disorders such as systemic lupus erythematosus, and women postpartum. Patients are managed acutely with replacement therapy (high-dose factor VIII, activated vitamin K–dependent coagulation factor concentrates, or recombinant factor VIIa), but long-term management may require immunosuppression with cyclophosphamide (Cytoxan) and prednisone and/or rituximab.[29,30] Management decisions in these patients are influenced by the severity of bleeding and the height of the titer of the inhibitor to factor VIII as determined by the Bethesda assay.[31-33] The Bethesda assay is a uniform procedure to perform an assay to detect a specific inhibitor to a blood coagulation protein. It requires a 2-hour incubation at 37° C of test plasma with normal plasma. Inhibitor titer is determined by the degree of dilution of test plasma to obtain a factor level of 50% normal. A complete discussion on performance and interpretation of this assay is seen in Schmaier and Miller.[34]

Alternatively, an isolated PT prolongation associated with bleeding usually indicates factor VII deficiency (see Chapter 139). Patients usually have partial factor VII defects since a complete deficiency is incompatible with life.[35] At times, defects in some common pathway proteins (fibrinogen and factors II, V, and X) may first appear as an isolated PT prolongation; if severe, these latter protein defects will yield prolonged PT and aPTT results. The reason for the former is that more sensitive PT reagents, those with an ISI of approximately 1, detect the defect before the aPTT.

In general, defects in the common pathway proteins (fibrinogen and factors II, V, and X) usually result in a prolonged PT and aPTT. When confronted with laboratory results demonstrating a prolonged PT and aPTT, the hematologist should first consider clinical situations that can affect these tests, such as anticoagulation therapy, disseminated intravascular coagulation (DIC), liver disease, vitamin K deficiency, or massive transfusion.[36,37] These general medical conditions are the most common causes of abnormal results in the two screening tests. Anticoagulation, unless the patient is faking medical illness, and massive transfusion are excluded by history.[38] Vitamin K deficiency is rare except in patients who are receiving warfarin therapy, are nutritionally depleted alcoholics, are having intravenous replacement without vitamins, have bacterial overgrowth in the gastrointestinal tract as result of antibiotic therapy, or, very rarely, have defects in transport proteins or enzymes for metabolism (see Chapter 128). There are several mechanisms by which liver disease can contribute to a prolonged aPTT and PT. Prekallikrein, factor XI, factor VII, and factor V are the first proteins to be decreased in liver disease. Abnormal fibrinogens often are produced in liver disease.[39] The TCT detects defects in fibrinopeptide A and B release, as well as polymerization defects. The reptilase time uses a snake venom enzyme to "clot" fibrinogen by liberating only fibrinopeptide A.[40] An abnormal TCT with a normal reptilase time indicates a fibrinopeptide B–release defect, an abnormality that gives very long aPTT and PT values but is not associated with bleeding (see Table 131-2).[18] The reptilase time also will not be altered by the presence of heparin and can be used to determine if a prolonged aPTT and TCT are the result of heparin.[38]

In addition to these general medical conditions, acquired disorders can present with the clinical laboratory phenotype of a prolonged PT and aPTT. Acquired deficiencies or inhibitors are also seen in a number of medical conditions. Systemic amyloidosis is associated with decreases in plasma factor X or IX as a result of adsorption of the coagulation proteins onto the amyloid protein.[41] In the former condition, the PT and aPTT may be affected; in the latter, only the aPTT is affected. Hypergammaglobulinemic states seen with multiple myeloma or Waldenström macroglobulinemia (immunoglobulin M) can be associated with inhibitors to coagulation protein function.[42] Dysfibrinogenemias are common in these patients because fibrinogen binds immunoglobulin.[18] These phenomena are recognized by performing specific factor assays against the one or more proteins affected at multiple dilutions of the patient's plasma. In general, as the factor assay is performed at lower dilutions (e.g., 50%, 25%, and 10% of normal plasma), the degree of inhibition of the coagulation factor reduces, suggesting that as the plasma is diluted, the effect of the inhibitor is lost. This coagulation test pattern is characteristic of a specific inhibitor to a coagulation protein.

Another acquired inhibitor that influences coagulation protein reactions is the lupus anticoagulant (see Chapter 143). This inhibitor represents antibodies directed to epitopes of proteins bound to certain phospholipids.[43] Lupus anticoagulants variably interfere with the aPTT and PT. Detection of the degree of interference depends on the nature of the commercial reagent. Characteristically a lupus anticoagulant will have a greater effect on a coagulation assay as the reagents, not protein, in the assay are diluted out.[44] For example, the degree of prolongation of PT or aPTT in a plasma sample will be greater at 1:50 dilution and 1:500 dilution of the assay reagent in a patient with a lupus anticoagulant than in a patient with a specific inhibitor to a coagulation protein.[44,45] In the latter case, the inhibitor level will change only when the patient's plasma, not the reagent for the assay, is diluted. Specific criteria have been developed to recognize lupus anticoagulants.[43,46,47] In general, assays that have some dilution of the coagulation reagent (dilute PT or tissue thromboplastin inhibition assay, dilute aPTT, dilute Russell viper venom time, or kaolin clotting time) are useful but are not specifically diagnostic for the condition.[43,45,46] Correction of the defect with excess phospholipids or platelet membranes is an additional characteristic of the disorder noted on clot-based assays.[43,48] However, no clot-based assay is diagnostic for lupus anticoagulants. All criteria also emphasize that the diagnosis is one of exclusion.[43,48] Serologic testing examining for antibodies to cardiolipin or β_2-glycoprotein I is additional immunologic testing the laboratory can use to meet criteria for diagnosis of antiphospholipid antibodies.[43] As indicated in Chapter 143, the serologic criteria for diagnosis of antiphospholipid antibody syndrome is assay evidence for a lupus anticoagulant or antibodies to phospholipids by any procedure that is positive when tested twice with a minimum 3-month hiatus between examinations.[43]

FACTOR-SPECIFIC COAGULATION PROTEIN TESTING

All specific coagulation factor assays of the intrinsic system (factor XII, prekallikrein, high-molecular-weight kininogen, factors XI, IX, and VIII) are measured via one-stage assays using aPTT as the assay platform.[15,49-51] These assays became readily available because of accessibility of specific factor–deficient plasma. For example, a factor VIII assay uses a mixture of aPTT reagent, factor VIII–deficient plasma, and patient (test sample) plasma. After incubation for more than 5 minutes, the time to clot is initiated by recalcification with calcium chloride. All coagulation factors of the extrinsic system and common pathway (factors VII, X, V, and II) are measured in assays using PT as the platform.[16,50,51] For example, a factor X assay is a mixture of PT reagent that contains tissue factor (thromboplastin), factor X–deficient plasma, and patient (test sample) plasma. After incubation for more than 5 minutes, the time to clot is initiated by addition of calcium chloride. The amount of factor present in a given patient sample is determined by comparing the patient sample against a standard curve made with 10% to 100% pooled normal plasma using the factor-deficient plasma and aPTT or PT reagent.

Coagulation-based assays are sensitive and specific. They are simpler to perform than antigen assays for each of the coagulation proteins. Additional assays such as the TCT and reptilase time specifically examine the integrity of fibrinogen.[17,39] Coagulation-based assays examine the function of the protein, antigen assays establish its presence, and, combined, these assays may detect protein with reduced function, but normal antigen levels. This pattern is classic for production of an abnormal molecule. Such a situation commonly arises when examining fibrinogen. The most useful means for determining the presence of an abnormal fibrinogen (dysfibrinogenemia) is to measure clottable fibrinogen and fibrinogen antigen on the same sample.[18,52] If fibrinogen clottability is less than 90% of the amount of fibrinogen antigen, the protein produced probably is functionally abnormal.[39,52] If performed for other coagulation proteins, antigen assays would aid in the diagnosis of abnormal proteins as well.[52]

Chromogenic assays also are used to measure certain enzymes (factor VIII, factor Xa, thrombin, plasmin, activated protein C) and

various plasma protease inhibitors (antithrombin, α_2-antiplasmin, C1 inhibitor, plasminogen activator inhibitor). In general, chromogenic assays precisely measure the activity of the protein of interest. However, a coagulant-based assay for a protein (e.g., protein C) will provide a more global result of its (e.g., anticoagulant) function. The drawback of coagulant-based assays is that the levels or function of other proteins influence the results. For example, a heterozygous factor V Leiden polymorphism gives an abnormal protein C coagulant assay but will have no influence on protein C activity if performed by chromogenic assay. The ability to neutralize the enzymatic activity of factor Xa or thrombin is the most reliable way to assay for the plasma level of anticoagulants, such as low-molecular-weight heparins (LMWHs) or unfractionated heparin (UFH), respectively.[52] Anti–factor Xa chromogenic assays provide the most reliable means to measure fondaparinux or rivaroxaban, provided each has its own standard curve. The direct thrombin inhibitors (argatroban, bivalirudin, hirudin, or dabigatran) can be assayed in plasma using an antithrombin chromogenic assay. With each agent, a unique standard curve using that drug also needs to be established by the individual laboratory.[53] Alternatively, an ecarin clotting assay can be established to measure direct thrombin inhibitors provided that a standard curve with each agent is constructed.[54] A dilute thrombin clotting time using dabigatran calibrators can also be used to determine plasma concentrations of dabigatran.

PRACTICAL APPROACH TO THE BLEEDING PATIENT WITH A COAGULATION PROTEIN DEFECT

Patients with abnormal results on coagulation assays can be evaluated by the differential diagnosis of an isolated aPTT abnormality, PT abnormality, or both. When presented with a prolonged coagulation assay, the differential diagnosis often is between a true deficiency and an inhibitor to a specific coagulation protein. Two approaches can be used to obtain a specific diagnosis.

A common practice when approaching the problem of determining specific coagulation factor defects begins with a mixing test of patient and normal plasma. Mixing studies based on the PT or aPTT are interpreted based on the fact that a 50% level of any coagulation factor alone gives normal PT and aPTT values. Both of these screening assays have hyperbolic curves, that is, a decrease in any one factor does not lead to a linear prolongation of either of the two assays. At 50% levels of any coagulation factor, global clotting assays will fall in the normal range.[55] Only with values less than 50% of specific factors will the PT and aPTT begin to prolong. The sensitivity of the PT and aPTT to prolongation with lowering of clotting factors varies depending on the factor and the reagent made by the manufacturer.[22] Thus if patient plasma is mixed 1:1 with normal plasma, the PT or aPTT should be normal if no factor is present in the patient plasma. If the mixture does not correct to normal, something in the patient plasma is interfering with the function of the protein in normal plasma.

Because screening assays for inhibitors are not standardized, a mixing study is a weak assay fraught with misinterpretation and, in many ways, is a much less attractive initial approach. Almost no studies provide evidence-based laboratory procedures for inhibitor screening assays. Some approaches to the use of mixing studies were developed for testing for lupus anticoagulants, which have their own peculiar aspects.[45-48] Critical issues in performing mixing studies is the ratio of patient plasma to normal plasma (1:1 to 4:1), the time of incubation from mixing to assay (immediate to 2 hours), and the assays used for measuring results (PT, aPTT). One critical investigation examined the sensitivity and specificity of mixing studies for assessing factor deficiencies and anticoagulants.[56] Patient and normal plasma were incubated at 37° C for 1 hour before assay in a ratio of 1:1 or 4:1 patient to normal plasma. On an aPTT mix of 1:1 with percent correction of 70% to 75% calculated using a specific formula (see reference for formula), the sensitivity and specificity in recognizing a factor deficiency or anticoagulant were 100% and 33% or 33% and 100%, respectively. When the percent correction was 50% calculated from a ratio of 4:1 patient to normal in the plasma mix for the aPTT, the sensitivity and specificity in recognizing a factor deficiency or anticoagulant improved to 88% and 100% or 100% and 88%, respectively.[56] Likewise, on a PT mix of 1:1 with a percent correction of 70% to 75% calculated using a specific formula (see reference for formula), the sensitivity and specificity in recognizing a factor deficiency or anticoagulant were 95% and 50% or 50% and 95%, respectively. When the percent correction was greater than 40% calculated from a ratio of 4:1 patient to normal in the plasma mix for the PT, the sensitivity and specificity in recognizing a factor deficiency or anticoagulant improved to 96% and 100% or 100% and 96%, respectively.[55] Further studies showed that assays performed after an immediate mix had lower sensitivity and specificity than those done after 1-hour incubation at 37° C. These investigations show the variability of mixing studies test performance and the pitfalls in translating their information into meaningful diagnostic data. Usually it takes 1 day to get inhibitor screening results back, hence delaying diagnosis. However, determining that an inhibitor is present only indicates that additional factor assays must be performed to isolate the specific protein against which the inhibitor is directed. With the identification that the level of a specific protein is low, specific inhibitor studies are needed to confirm the diagnostic impression and determine the inhibitor titer so that management can be planned.

As a second approach to diagnosis of a coagulation protein defect, the abnormal factor can be identified by performing all relevant coagulation factor assays indicated by the abnormal PT and aPTT. If any one test value is decreased, then a specific coagulation factor inhibitor assay for that factor can be performed. One can argue that an excess number of specific assays is being performed, but in most developed clinical institutions these assays are automated and can be performed more efficiently in batch fashion than piecemeal with sequential ordering. The value of such an approach is the shortened time to a specific diagnosis. If more than one factor is found to be low using such an approach, then efforts are made to determine the global reason for the result. Finding a decrease in a single factor by any initial approach requires more effort to perform assays for a specific factor inhibitor. One general approach to a specific inhibitor study can be performed by mixing various ratios of patient plasma to normal plasma (e.g., 1:1, 2:1, 4:1, 1:2, 1:4), incubating the samples for 2 hours at 37° C, and then assaying the level of the specific factor in the mixture.[57] Simultaneously, the patient plasma and normal plasma used in the mixing study are incubated under the same conditions. At the time of assay, the percent activities of the specific factor under study in the normal plasma, patient plasma, and each of the mixtures are obtained. If the *observed value* at any given ratio of patient plasma to normal plasma is less than the calculated *expected value* of mixing the two plasmas in the various ratios (e.g., 1:1, 2:1, 1:2), then one can conclude that an inhibitor present in patient plasma was transferred to the normal plasma sample. For example, if there is 100% activity (1 unit/mL) of the factor being studied in an undiluted sample, a 1:1 dilution of normal plasma with factor-deficient plasma should give an activity level of approximately 50%. If the same normal plasma was incubated 1:1 with patient plasma and the activity was 32%, one should conclude that something in the patient plasma transferred and inhibited the factor's activity in normal plasma, which is the definition of an inhibitor. This approach is a general, nonquantitative method for assessing a coagulation factor inhibitor.

An alternative specifically quantitative method for determining inhibitors to any coagulation factor can be developed for all coagulation factors using a modification of specific inhibitor assays used to characterize factor VIII inhibitors (Bethesda assay).[31-33] This approach is preferred because it standardizes assay performance and method for reporting inhibitor assay results. Given the vagaries of general mixing studies for inhibitors, my approach has been to determine if a single coagulation factor is affected when the screening tests are abnormal and then determine if there is a specific inhibitor to the activity of that factor using a standardized approach to a specific factor inhibitor assay.[31-33]

SCREENING TESTS USED TO RECOGNIZE PATIENTS WITH DISORDERS OF PLATELET NUMBER OR FUNCTION

Recognition of platelet function disorders is critical to any hemostatic evaluation (see Chapters 130, 132, and 161). Knowing the platelet count is essential because thrombocytopenia alone may increase bleeding risk. Obtaining a detailed medication history from patients is important to ascertain the mechanism of action of each agent and its possible influence on assays for platelet function. It is clinically not useful to document abnormal platelet function in a patient taking interfering medication. Screening tests for platelet function testing have been developed; each has advantages as well as disadvantages. The screening tests for platelets are as follows:

1. *Platelet count.* This assay measures the number of platelets in 1 μL of blood. It is used to exclude a quantitative platelet defect as the cause of a bleeding disorder. Causes of thrombocytopenia are discussed in Chapters 134 to 136.
2. *Bleeding time.* To perform this assay, the forearm is pierced, and the time until bleeding stops is measured. Specific devices have been manufactured to perform this assay. The bleeding time is a very qualitative assay influenced by technique, skin characteristics, platelet count, and platelet function.[58] It should only be performed by experienced technologists. In general, it should not be performed on any patient with a platelet count less than 100,000/μL because a low platelet count alone can lead to prolongation of the bleeding time. The bleeding time assay is not a good predictor of surgical bleeding.[59,60] It is seldom useful when performed on a hospitalized patient. However, in the outpatient setting for an individual who has a bleeding history and is not taking any medications, an abnormal bleeding time may provide useful information. It may predict whether more costly von Willebrand factor studies and platelet aggregation and secretion studies will be useful for the diagnosis of a bleeding state. If thrombocytopenia is not present, the differential diagnosis of the long bleeding time includes von Willebrand disease and platelet function defects. However, one can equally argue that a normal bleeding time does not exclude von Willebrand disease or platelet function defect. Patients with Ehlers-Danlos syndrome, osteogenesis imperfecta, and scurvy may have variable prolongation of bleeding times that are not necessarily due to platelet dysfunction.[61-63]
3. *High-shear platelet function analyzers.* Several automated platelet function analyzers have come into use as screening tests for platelet function abnormalities. They have been proposed as replacements for the bleeding time as a diagnostic assay. Each method is unique to and should be evaluated against the wide range of congenital and acquired platelet function disorders before it is accepted as a screening assay. One product, the platelet function analyzer PFA-100 (Siemens, Deerfield, Ill), has been best evaluated and is most widely used.[63-65] In citrated whole blood, the PFA-100 measures the "closure time" required for platelets to adhere to agonist-coated membranes and aggregate under high shear stress (5000 to 6000/sec). It is a novel technology and not analogous to the bleeding time or light transmission platelet aggregometry. Two cartridges are available: collagen–adenosine diphosphate (ADP) and collagen-epinephrine coated membranes. Platelet function is measured as a function of the time needed to occlude the aperture, termed "closure time." Abnormal closure times are longer than the mean values of laboratory-specific values for normals. Each laboratory that uses this technology must determine its own normal values because of influences of different collection tubes and anticoagulant concentrations. Test results can only be interpreted as normal or abnormal. The assay does not make a specific diagnosis (e.g., von Willebrand disease). The PFA-100 may be useful to screen for individuals with von Willebrand disease, Glanzmann thrombasthenia, and Bernard-Soulier syndrome but may be less sensitive to primary platelet secretion defects and storage pool disorders.[66-70] Any abnormality detected by the PFA-100 requires specific testing for von Willebrand disease and platelet function disorders for diagnosis.

INTERPRETATION OF SCREENING TESTS OF PLATELET FUNCTION

Abnormalities on one or more of the screening tests in a patient with a normal platelet count usually suggests von Willebrand disease or a defect in platelet function. Of note, von Willebrand disease or platelet function defects leading to bleeding can be present even with normal results for one or both of the screening assays. At present, no screening assay can exclude the diagnosis of von Willebrand disease or a platelet function defect. If the clinical history is compelling but the screening test results are normal, more definitive von Willebrand factor or platelet function testing is needed. Likewise, if screening test results for platelet function abnormalities are abnormal, the consulting physician has the onus to diagnose or exclude von Willebrand disease or a platelet function defect. Thus once medication or nonprescription drug use is excluded, more sophisticated, specifically diagnostic studies for von Willebrand disease and a platelet function defect are needed for most patients requiring invasive procedures. In general, I do not use the bleeding time or PFA-100 to screen patients for von Willebrand disease or platelet function defects on consultation. If clinically appropriate, complete von Willebrand factor and platelet function studies are performed. In general, 1 of 10 patients in this diagnostic category have a platelet function defect. The majority of individuals fall into the category of von Willebrand disease. Von Willebrand disease is discussed in Chapter 140. Its diagnosis is made by abnormal results for studies of von Willebrand antigen, von Willebrand factor activity (ristocetin cofactor assay and collagen-binding assay), and von Willebrand factor multimers. Some patients with von Willebrand disease also have a reduced factor VIII assay, presenting with a long aPTT. Certain subtypes of patients with von Willebrand disease (type IIB or platelet-type) have a lower threshold to agglutinate and aggregate to ristocetin (0.3 to 0.6 mg/mL) in platelet-rich plasma; normal individuals do not respond to this concentration of ristocetin. However, all normal persons respond to 1.0 mg/mL and higher concentrations of ristocetin added to platelet-rich plasma.

In addition to evaluation for von Willebrand disease, individuals with an abnormal bleeding time or PFA-100 result may require evaluation with platelet aggregation studies. Two forms of platelet aggregation studies are available: light transmission aggregometry in platelet-rich plasma and impedance aggregometry in platelet-rich plasma or whole blood. Light transmission aggregometry in platelet-rich plasma is the gold standard of platelet function testing[71]; impedance aggregometry is less well characterized.[72] Whole-blood impedance aggregometry to some extent is a screening study as well. When performed in conjunction with platelet secretion, either of ATP or serotonin, light transmission aggregometry can be diagnostic of several well-characterized platelet function defects and can characterize defects in others (see Chapters 127 and 132). The procedures for light transmission aggregometry have been reviewed.[73-75] Because of the wide variability in how light transmission aggregometry is performed in clinical laboratories, efforts have been made to develop minimal standards for the performance of platelet function testing in clinical laboratories.[76,77] In light transmission aggregometry, the absence of platelet aggregation in response to physiologic platelet agonists is indicative of Glanzmann thrombasthenia (defects in integrin $\alpha_{IIb}\beta_3$), whereas absent agglutination/aggregation in response to ristocetin suggests Bernard-Soulier syndrome (defects in glycoproteins Ib, IX, and V) or von Willebrand disease. Platelet storage pool disorders can be diagnosed if platelet light transmission aggregometry is performed simultaneously with studies that include measurement of proteins within or released from platelet α-granules or dense granules or measurement of granule membrane proteins (e.g., P-selectin) that become surface expressed after cell activation. Platelet activation defects, such as that induced by aspirin, can be diagnosed as well using this combination of techniques (see Chapter 132). Finally, with appropriate monoclonal antibodies, flow cytometry is used to completely examine the surface expression of platelet glycoproteins and the activation state of the cell.[78] It is important to realize that

evaluation of all important platelet receptors, granule release, and formation of activated platelet receptors is adequately performed by flow cytometry, supplanting the need for platelet aggregation and secretion studies.

BLEEDING DISORDERS NOT RECOGNIZED BY SCREENING TESTS FOR COAGULATION PROTEINS OR PLATELETS

A few rare bleeding disorders are not recognized by routine blood coagulation and platelet screening tests (see Table 131-2). These entities include, in order of frequency, factor XIII defects, α_2-antiplasmin defects, plasminogen activator inhibitor 1 defects, and α_1-antitrypsin Pittsburgh. Factor XIII deficiency can be congenital or acquired, especially after isoniazid therapy.[79] α_2-Antiplasmin defects and plasminogen activator inhibitor 1 defects produce hyperfibrinolytic states as a result of reduced inhibition of plasmin and tissue plasminogen activator or urokinase, respectively.[80-82] α_2-Antiplasmin deficiency can be acquired in acute leukemia or other activated coagulation states.[81] Deficiency or abnormal forms of plasminogen activator inhibitor 1 also are associated with a bleeding state.[81] α_1-Antitrypsin Pittsburgh is an exceedingly rare bleeding disorder caused by a mutation in antitrypsin that results in potent thrombin inhibition, preventing clot formation.[83]

OTHER ACTIVITIES FOR HEMOSTASIS LABORATORIES

Thrombosis Evaluation

In addition to the diagnosis of bleeding disorders, the hemostasis laboratory is important in the evaluation of prothrombotic states (see Chapter 142). Evaluation of prothrombotic states serves the patient in many ways. In individuals with idiopathic thrombosis, recognition of a specific molecular or protein defect may be important in determining the duration of anticoagulant therapy. Certain prothrombotic states (e.g., antithrombin, protein C, and protein S deficiencies; antiphospholipid antibody syndrome) may confer higher risk for recurrence and thus suggest long-term anticoagulation after the first event. Less severe prothrombotic states (e.g., factor V Leiden and prothrombin 20210 polymorphisms, functional defects in fibrinogen and plasminogen) do not in themselves confer high risk for thrombosis but when conjoined with another risk factor may confer higher risk. Knowing this information helps patients engage in risk modification activity (e.g., stop taking oral contraceptives). Finally, 18% of patients without a family history of thrombosis and 30% to 40% of patients with a family history may have an identifiable molecular or protein risk factor for venous thrombosis.[84] This information helps many patients deal with anticoagulant management issues after they present with idiopathic thrombosis.

Monitoring Acute Hemostatic and Thrombotic Conditions

In addition to the diagnosis of hemostatic and thrombotic disorders, the coagulation laboratory has the function of monitoring patient therapy. Patients receiving UFH and warfarin are monitored using the aPTT and INR, respectively. New monitoring roles are being established for these facilities. This section is divided into two parts: monitoring of anticoagulation therapy and measurement of activated coagulation.

Anticoagulation monitoring is an increasingly larger activity of hemostasis laboratories. In addition to UFH and warfarin monitoring using clot-based assays, LMWH monitoring is an important activity in hospitalized patients. This monitoring is especially important in patients who are obese, in those who have renal function compromise, and in patients before elective surgery.[85] Anti–factor Xa assays for monitoring LMWHs can be developed against each agent using the WHO's LMWH for the standard curve.[53] Each of the new anticoagulants (fondaparinux, dabigatran, rivaroxaban) requires unique standard curves for assay development on the appropriate chromogenic assay.

Monitoring of activated coagulation states and their amelioration with treatment is another activity of the specialized hemostatic laboratory. The classic activated coagulation state is DIC (see Chapter 141). DIC is a clinicopathologic state associated with tissue destruction as a result of infectious, traumatic, obstetric, malignant, and connective tissue disorders. The two forms of clinical presentation are an *acute* form that is a hyperfibrinolytic state and a *subacute* form that is more indolent. In the acute form, aPTT and PT are elevated, and the fibrinogen and platelet count are low. In the subacute form, aPTT, PT, and platelet count may be normal or slightly low, and fibrinogen count can be normal or even elevated. Finding a prolonged PT and aPTT with a reduced fibrinogen and platelet count usually indicates DIC in the hospitalized patient until proven otherwise.[86] This clinical laboratory phenotype of DIC most probably results from a secondary hyperfibrinolytic state and is the form of DIC most commonly recognized. The biochemical diagnosis of DIC then is simplified to finding evidence of simultaneous thrombin and plasmin formation. The D-dimer is a plasmin-proteolyzed fragment of insoluble, cross-linked fibrin.[87,88] It is a confirmatory assay for DIC in the appropriate clinical condition. Insoluble fibrin results from thrombin cleavage of soluble fibrinogen and cross-linking of fibrin by thrombin/activated factor XIII. Presently a scoring system to aid in the diagnosis of DIC is available.[89]D-dimer elevation characterizes DIC but is not specific for it. Assay results are positive in patients in postoperative states, with resolving hematomas, and after large-vessel or pulmonary thrombosis. Positive results of a D-dimer assay also have become an adjunct to the clinical diagnosis of pulmonary embolism.[90]

In addition to DIC (see Chapter 141), other hematologic states such as antiphospholipid antibody syndrome (see Chapter 143), heparin-induced thrombocytopenia and thrombosis syndrome (see Chapter 135), and warfarin–skin necrosis with protein C deficiency (see Chapter 129) also are activated blood coagulation states. Physicians may find that monitoring the degree of the activated blood coagulation state is useful as a guide to therapy. In addition to the D-dimer, other assays that could be used to monitor an activated blood coagulation state include prothrombin fragment 1.2, thrombin-antithrombin complexes, or thrombin generation assays.

Finally, heparin-induced thrombocytopenia presents unique opportunities to coagulation laboratory testing for both diagnosis and monitoring of the activated blood coagulation state. Laboratory diagnosis and monitoring the effectiveness of therapy for heparin-induced thrombocytopenia is discussed in detail in Chapter 135.
